If the disease demands a special condition of tissues, it is scientific and proper treatment to prevent its development by so fortifying the tissues as to give them immunity against the attacks of the one known causative agent. Prevent the acquirement of the diathesis, change the diathesis when acquired, sums up preventive treatment. Make the wives, relatives, and nurses of the consumptive the real patients; keep up their resistant powers, and they will not develop tuberculosis. The disease, once acquired, is generally beyond our control, but to prevent its development is feasible.

Like the East Indian who strives to secure the favor of the gods of all creeds, let us bow to the bacillus and destroy the sputa, ventilate and cleanse the apartment used by the sick. Only good to well and sick can result. Exceptionally, it might be well, for one thrown into intimate sleeping association with a consumptive in a room poorly ventilated, to wear an inhaler.

The experience of generations may have shown that only one seventh of us acquire tuberculosis, but "only one seventh of us" is a large number. Such mortality justifies all proper precautions against the bacillus.

This anti-germ preventive treatment is so enticing in its simplicity of statement and promised thoroughness that one finds it difficult not to follow it, unquestioning, wherever it may lead. Here is the cause. Kill the cause and destroy the disease. But who can contend against the myriad spores incorporated in earth and air through the ages of the existence of phthisis? Koch says: "It is probable that the bacillus clinging to particles of dust is breathed into our lungs at every inspiration." We stir them up as we walk the streets; they are in our lungs; nay, more, mounted on the white-blood corpuscles, the bacillus navigates and circumnavigates the shores of the arterial ocean watching for a favorable spot to disembark and settle.

Perhaps its home is not alone the animal tissues. Koch has proved that the anthrax bacillus has a vegetable habitat. May not the same be true of the *Bacillus tuberculosis*? We may kill the developed bacillus, but the spore is probably well-nigh indestructible, like its kindred.

For the reasons given, in view of the still unsettled state of

our pathological and anatomical knowledge on the subject, and in view of possible further bacterian discoveries, any extreme anti-germ preventive treatment can be pronounced possibly unscientific, probably deceiving, misleading and disappointing, certainly cruel and utterly impracticable.

In munitive therapeutics we deal with more manageable factors than bacilli and spores. An essential of success is an early recognition of the necessity for medical supervision. The family doctor can best conduct the treatment. Proper food, dress, sleeping-room, exercise, habits, climate, and medication, are our protective agents. What we mean by each must be fully and clearly explained in the case of any individual patient. With different patients we shall need to insist on different factors. The usual subjects for medical supervision will be the weakly with phthisical heredity or of acquired susceptibility. The earlier it is commenced the better.

About proper food it is sufficient to say that the nutrition must be kept at its highest. Directions will vary with the patient.

Clothing must be sufficient and adapted to the climate. The vagaries of fashion and ignorance will not allow us to forget this factor.

More than a third of one's life is spent in the bedroom. No treatment is complete which ignores that sleeping apartment—its size, ventilation, and exposure. This is the work of a sanitary engineer, but the physician must take his place, however imperfectly. Occasionally excess of ventilation has to be corrected. Cold air is not always pure air.

Regular exercise in the open air is of the first importance. I urge a patient while in the open air often to throw back the shoulders strongly and inspire deeply, remembering that Freund showed in 1859 that an ossification of the cartilages of the first ribs might occur early in life, and prevent or retard the development of the thorax and lung tissues. Singing or elocution may be recommended. Gymnasiums have their uses.

An efficient change of climate does not require removal to a great distance necessarily. All the change needed may often be gained by removal from low to high ground, from a place exposed to one sheltered, from an overcrowded ward to one less thickly populated. Dr. Bowditch once showed that phthisis was more prevalent where the soil was clayey than where it was light, admitting ready oxidation. A slight remove may secure this lighter soil.

The good in munitive therapeutics is shown in one instance, known to many. I allude to Miss Harriet Hosmer. All of her brothers and sisters had died of consumption, and her father determined to try what out-door life and exercise would do for her. By this treatment she was so fortified that she alone resisted the influences to which the others had succumbed. At least such is the fair inference from the full history. The great foe to out-door life is the system of public-school education with its attendant confinement and overwork, its poorly lighted and ventilated rooms.* Prevent the injury this system can work. As our

* Last autumn and winter I made some eighty examinations of the air in school-rooms. I found as high a percentage of CO₂ in one room

best work is to be done with the young, the utter subordination of physical to mental growth can hardly be too much insisted upon. Many pages could be written on this head.

Niemeyer mentions the astonishing results he has noted after taking his patients out of school.

Medication is indirect; all catarrhal and other drains upon the strength must be promptly checked. Greater attention must be given to even slight ailments than would be paid to them occurring in the stronger. Perhaps all have not seen Catlin's "Breath of Life." In this eccentric book he embodies what he deems the best single piece of advice that can be given to mankind in these words: "Shut—your—mouth." Our patients must be nose-breathers, and we should see that all impediments to nasal breathing are removed. Suppurating glands should be extirpated. The advisability of removing the non-suppurating is questionable.

With our older patients we have to consider the occupation, and perhaps recommend a change thereof, or precautions in its pursuit. For example, stone-cutters and others similarly employed should habitually wear inhalers. I feel most confident that in time none but the foolish will attempt the pursuit of many occupations without such common-sense preventives of disease, not to mention depressed vitality and discomfort. I remember, when a lad, improvising an inhaler out of two folds of a moistened woolen comforter and completing a dusty job without the discomfort experienced at its commencement. For the poor printer and those of similar callings, whose danger lies in bad air and close confinement, we can not do so much, and yet can do something by good advice.

THE DEBT OF SCIENCE TO THE LATE SURGEON-GENERAL CHARLES H. CRANE, U. S. ARMY.

By R. W. SHUFELDT, M. D.,
ASSISTANT SURGEON, U. S. ARMY.

Nearly a year has passed over our heads since the subject of this article was so suddenly and for ever removed from among us. At the time following his death there appeared in the usual places short accounts of his life and military career. All of these spoke in the highest possible terms of this side of General Crane's character, but, so far as my observation goes, no one has as yet written a line to commemorate his good deeds in another and still more important field. In my opinion, not only is the science of this country, but the science of the world at large, under deep and lasting obligations to this man and officer. Many of my scientific *confrères* may raise their eyebrows at this broad statement, and at once ask the questions, What ground have you for such an assertion? How is it possible for one, probably thoroughly unscientific himself, in the technical sense of the word, to have influenced science either for good or bad to any such marked degree? In short, what did General Crane do at any time in his life for science to merit

as 5-6 in 1,000 volumes. My findings prove again how depressing is school life.

any special notice? It will be my aim in this article, however imperfectly I may accomplish it, to satisfactorily answer these several questions and prove the foregoing statement to be by no means an empty one.

General Crane in very many particulars was great. He was a man of extraordinary will and determination, on some occasions almost carried to the point of obstinacy, and no doubt this would have often occurred had not these traits been under the most perfect control of a large, kind heart, and the highest appreciation of the sense of justice. His mind was of the most orderly cast, and his knowledge of organization keen. In habit he was cultured and refined, and possessed of, in more particulars than one, a good education. We must add to these characteristics another of which he seemed to be a very master, and this was his peculiar ability, sometimes upon the shortest of acquaintance, to read a man's entire worth; and, with an intuition almost unerring, to estimate the character of work he was best able to perform, or the position he was best fitted to fill. It is easy to be seen that a gift of this kind was of the highest value, not only to himself, but to those subordinate to him in the office that he occupied.

Such, in brief, was the man who for many years held the Assistant Surgeon-Generalship of the army, and, for a much shorter time, the Surgeon-Generalship. And, as it is now a matter of history, it is not to be wondered at that one possessed of such positive features in his character should largely influence the direction of affairs of the department of which in reality he was the virtual head. During these seventeen or more long years there was no ambition that General Crane held nearer to his heart than the perfection, using the word in the widest sense, of the medical corps of the army. Upon this he brought all and his best influence constantly to bear, using every power at his command to effect this end. Not many of these years of his *régime* had passed before his knowledge of the very nature, temperament, and capacity of every individual officer in the corps was complete, and every requirement of the whole clear to his mind; this knowledge ever ripened, too, with his years and experience.

Early in his career he became convinced that at least one element of the success of his object lay in the appreciation of the fact that the opinions of the world at large were by no means to be ignored. This conviction became a settled fact in his mind, and one of the axioms for his guidance, due to his long residence at the capital and his contact with scientific people of the country and wise men holding analogous positions in civil life.

General Crane never seemed to lose sight of the fact that the great secret of success of any organization lay in applying each and every individual composing it to the kind of work or duty he was best suited for and capable of performing. Coming from nearly all parts of the civilized world, the recipients of various educations and trainings, it is not at all surprising that he found he had many casts of men to deal with, and men, too, of correspondingly diverse natures and abilities. These, however, through one method or another, he seemed to have acquired almost a perfect knowledge of, undoubtedly aided by his own powers of ob-

servation and peculiar ability in his estimation of the characteristics of each individual officer and the needs of the corps.

No one could have given a more correct answer to the question so pertinently asked by Huxley in one of his addresses than General Crane. "Do you mean to say that there is no difference between the habit of mind of a mathematician and that of a naturalist? Do you imagine that Laplace might have been put into the Jardin des Plantes, and Cuvier into the Observatory, with equal advantage to the progress of the sciences they professed?"

If he discovered in an officer those traits that distinguished him above his fellow-officers as being peculiarly fitted as a surgeon, then he placed him where he could amputate and operate to his heart's content. It was sure in the long run to bring a return that would reflect credit upon the corps. Another is cast in a widely different mold; he is a chemist, and perhaps in many ways unfitted to be a surgeon—nay, may even have a great dislike for such work; then into the laboratory he goes, with all the facilities that the service could afford him. Another, as he has passed from post to post in his frontier duty, has shown a *constant* desire to report upon the hygienic conditions—the effects of climate, state of sewerage of buildings, air-space of hospitals, composition of foods and waters, and what not—then a position is given this officer so that all that was in him could be utilized. It was bound to bring its good returns, and certain to increase the efficiency of the whole.

If any officer developed a surplus amount of energy that was likely to carry him beyond the bounds of the sphere of action nature had designed him to play his part in, then no one sooner than General Crane applied all the rigor of military law to restrict such a luxuriant growth.

No member of the department under him was ever allowed, whatever his capacity might be, to absorb all the openings the corps had to offer.

Twice in conversation I learned from him how he regretted the chain of circumstances that threw Dr. Coues out of the army, and he said: "I believe I am right in holding him in his position, and I mean to do it as long as my influence will effect it." On the other hand, when any officer exhibited an inclination to improve the gifts he had been naturally endowed with, in any way whatever, General Crane was the first to second his efforts. To illustrate this, I must be permitted to quote a few lines from a personal letter from him that I still have in my possession and prize most highly. It is written in his own hand, and sent me on his reception of a bound copy of some of my earlier anatomical writings. In it he remarks: "It is always very gratifying to me to encourage, as much as possible, the younger members of the medical corps in any work they may undertake which promises to reflect credit on the corps and on themselves individually. It gives me much pleasure to congratulate you on the many excellent contributions you have submitted since your entrance into the Army Medical Corps, and, wishing you every success in the future, I am, etc." In my library I keep a great leather-bound book, in which I preserve many letters from eminent men who, upon one occasion or another, have in their own hand encouraged me

in a similar manner. As I say, this letter of General Crane's was received by me several years ago, when I was correspondingly younger; but so much did I esteem it at the time as an evidence of encouragement and approval on the part of the official head of the corps that I did not hesitate to consign it a place in my old volume. It must be remembered, too, that in this conservatory of mine these letters that I have spoken of bear the signatures of such men as Darwin, Huxley, Sir Richard Owen, England's anatomists; Alphonse Milne-Edwards, the physiologist of France; Alfred Russel Wallace; Pelzeln, of Austria; Joseph Leidy and Professor Baird; Collett, of Norway; J. V. Barboza du Bocage, of Portugal; Cope and Marsh, of our own country; Gegenbaur, E. Ray Lankester, Coes, A. Agassiz, Allen, and a host of others.

Such a courtesy, coming from the man General Crane was, is not likely to be forgotten by any officer, young or old, and seems to me would rarely have any effect other than to brighten his life in the service and spur him on to greater endeavor.

It was largely through General Crane's efforts that the great expeditions west of the one hundredth meridian, during the years of 1871-'74, were supplied with medical officers of the army particularly distinguished in the natural and other sciences, and it would be almost impossible to estimate the valuable results that accrued to science and the knowledge of this country that flowed therefrom in consequence.

Dr. Coes is largely indebted to the same source for what he has been enabled to do for us in American ornithology and general zoölogy.

Another large volume contains the reports upon the climate, physical surroundings, and natural history of the military posts, while another, equally large, is devoted to the hygiene of the same stations. For both of these—the work of medical officers of the army, the outcome of the same administration—this officer was largely responsible. They stand among the first glimmerings of light science possessed of our immense Western country. In another direction appeared monographs upon medical and surgical subjects, transportation of the wounded in the field, bibliographies, and other great quarto and handsomely illustrated volumes. The impulse they have given to the profession at large is simply enormous and incalculable.

To review, I think we may say in conclusion that it will be unanimously acceded that science must ever be under the greatest obligations to the late General Crane, of the United States army, for the way he fostered and cared for her votaries who were under his charge, and the wisdom he displayed throughout his administration, which brought the Medical Department of the Army to such a high state of perfection that it came to be respected, both at home and abroad, for its efficiency, as well as the professional and scientific works it gave to the world.

Contagious Pleuro-pneumonia among Cattle in the West prevails to such an extent that the Chief Inspector of the Canadian Cattle Quarantine is said to have recommended that the Dominion Government prohibit the importation of cattle from the United States into Northern Canada for breeding purposes.

A CASE OF INTESTINAL OBSTRUCTION, WITH VOLVULUS, REMOTELY CONNECTED WITH OVIARTOTOMY.

BY J. W. SHIVELY, M. D.,
KENT, OHIO.

I AM led to report the following case not because it possesses any special interest, viewed simply as a case of mechanical obstruction, but because it followed as a remote consequence, or what might be termed a delayed accident, of ovariectomy. And to my mind it has a further interest in that it furnishes a forcible argument in favor of surgical interference in cases of undoubted obstruction of the bowels. Had I profited by that radical yet sound procedure, the life of my patient might, perhaps, have been saved; at least the satisfaction would have been mine that the proper thing had been done, and that matters thereby had been made no worse.

I may state here that my patient had an ovarian tumor removed, some five or six years previous to her last illness, by Dr. Dunlap, of Springfield, Ohio. I believe the operation was a very satisfactory one, and she made a speedy recovery. But her husband has since informed me that his wife, after the operation, was greatly troubled with constipation, and subject to frequent attacks of colic. She was in the habit of using cathartic pills freely to relieve the former condition—in fact, she had become an inveterate "pill-taker." Yet, notwithstanding this, she was strong and robust, and enjoyed life equal to any, apparently. But to proceed with the case:

On the 8th of August, 1883, I was called to see Mrs. M., a bright mulatto, aged about forty-five years, who, it was said, was sick with an attack of "colic." On my arrival at the bedside I learned from my patient that, on the morning of the 5th, she took a dose of cathartic pills, which operated freely in the afternoon. In the evening she partook of some ice-cream, and soon thereafter she was taken with violent colicky pains. Her family physician was sent for, who had attended her a number of times before in similar attacks. He pronounced it "spasmodic colic," and administered a hypodermic injection of morphine, which afforded speedy relief. On the following day, however, the pain returned, accompanied by vomiting, and, for reasons not clearly stated, she sent for a homeopathist; but, not obtaining the relief she sought, after a trial of twenty-four hours, she called me in.

I found her suffering with severe pain about the umbilicus, vomiting every fifteen or twenty minutes, with an anxious look, feeble pulse, and great prostration. There was no fever, no tympanitis, nor tenderness on pressure over her bowels. I examined her carefully, thinking there might be strangulation from an undetected hernia, but I found nothing. I gave her a mixture of morphine and bismuth with camphor-water every two hours, and ordered the nurse to administer a copious enema of warm water, and afterward to apply hot fomentations. The next day, August 9th, she seemed greatly improved, the pain and vomiting had ceased, and she remarked that she felt "quite like herself" again, and "almost well." The enema, however, had failed to bring away any stool. She objected to the mixture I had prescribed the day before, so I substituted in its place

pulv. opii, in moderate doses, every four hours. The fomentations were continued.

August 10th she was worse again. The pain and vomiting again returned as bad as ever. She looked pinched, and was very uneasy. She begged me to give her something to move her bowels, declaring that if they were only moved she knew she would soon be better again. Being still uncertain in my own mind as to the true state of things, and influenced by her importunities and by her previous history, I determined, if possible, to evacuate her bowels. To this end I introduced a rubber tube into the rectum as high up as I was able (about eighteen inches), and fitted to it a Davidson's syringe. I then slowly and steadily forced up all the warm water I could, or until the resistance of the sphincter was overcome by the internal pressure. I repeated this operation three or four times, but no fecal matter came away. I now felt convinced that there was mechanical obstruction of the bowels, but the absence of tympanites and tenderness, usually so prominent in these cases, somewhat puzzled me. I gave her large doses of opium, and all the ice she desired to quench her intense thirst.

August 11th she vomited stercoraceous matter, her pulse being barely perceptible at the wrist, and her surface covered with a cold, clammy perspiration. Her mind was clear until death, which occurred on the evening of the 12th, being sick just one week.

Impressed with the idea that the obstruction was in some way connected with the former operation, I requested permission to examine the body after death. This was granted, and twenty hours afterward I made a *sectio cadaveris*. On exposing the abdomen, a long white cicatrix could be traced from the pubes to the ensiform cartilage nearly—the line of the former cut for ovariotomy.

At its lower end, about two inches above the pubes, a discolored spot, of half the size of the hand, was visible. It seemed to be in a state of gangrene, and ready to burst through; but, on closer inspection, it was found to be simply discolored from changes that had taken place within. Suitable incisions were now made so as to expose the bowels *in situ*, and it was soon discovered that the bowels had become adherent to the cicatrix at the point of discolored area mentioned. There were also extensive adhesions of the intestines to the sides and posterior wall of the abdomen, binding them firmly down, and doubtless from this cause the usual appearance of tympanites was prevented.

The intestines and cavity nearly everywhere gave evidence of former inflammatory processes.

But the most interesting discovery made was that a portion of the ileum, about eighteen inches above the cæcum, was adherent to and incorporated with the cicatrix—corresponding to the lower angle of the original wound—and that around the short portion, between this and the cæcum, a loop of small intestine was twice twisted, forming a kind of knot, and a complete and effectual barrier to the passage of the intestinal contents. The tegumental or cicatricial covering of the bowel at the point of adhesion was surprisingly thin. I have no doubt that during life the contents of the bowel might have been both felt at this point and seen, as they were forced along by the peristaltic action.

In reviewing the case several conclusions may be postulated.

1. That the bowel, by some unhappy chance during the healing of the cut for ovariotomy, became adherent to the cicatrix.

2. The bowel being thus fixed, the normal peristaltic

action was at this point interrupted, causing thereby the habitual constipation complained of, and, through errors of diet or habits, temporary obstruction—the so-called fits of spasmodic colic—were brought about.

3. The proximate cause of death was the knot or twist in the intestine occasioned by the violent action of the cathartic, assisted, probably, by some favorable position of the body, while the remote cause was the unfortunate adhesion of the bowel to the wound made for the ovariotomy.

4. That in this case no possible benefit could have been received from any treatment save that which surgery might have given—namely, the opening of the abdominal cavity and the disentanglement of the bowels.

A CASE OF MISSED ABORTION.

By J. B. TODD, M. D.,

PARISH, N. Y.

THE trouble that missed abortion may cause a patient and the blunders and errors of diagnosis that it may cause a physician to make are sufficient reasons why I should report the case that came under my observation. The fact of its not being recognized easily caused in this case a very annoying blunder in diagnosis and consequent mental suffering in the patient.

Mrs. B., aged thirty, married thirteen years, has had three children and two miscarriages. She became pregnant seven months ago, at which time she suffered terribly with nausea for six or eight weeks, when, in her words, she "had an abortion, only nothing came away." She was under the care of a physician for four weeks at that time, suffering much pain and flowing some all the time. Her attendant made no examination, but told her that she had had an abortion, and that the fetus and membranes had been discharged in small pieces so that they had not been noticed on the napkins.

She recovered so that she was around, but had much pain and weight in the back and loins, and occasional slight hæmorrhages. She finally consulted an eminent specialist, who diagnosed a malignant growth and advised its removal at once. This alarmed the patient very much, and she consulted her regular attendant, Dr. Low, of Pulaski, who diagnosed a tumor but wisely advised her to delay an operation.

I was called hastily, March 27, 1884, to relieve severe pain that she was taken with an hour before. I was told that she had a tumor, that it was thought to be cancerous, and that the pain she was suffering from came from it.

On examination, I found the hollow of the sacrum occupied by the body of the uterus, which was very hard and perhaps two inches and a half in its transverse diameter; the os was rigid, although dilated to the size of a nickel.

I easily introduced my finger, and could feel something protruding through the internal os, which had the feeling of a bag of waters presenting. I informed the patient that she was about to abort; she was greatly surprised, and told me that it was impossible, for she had menstruated for the past five months, and had no symptoms of pregnancy.

Notwithstanding all this, I held to my opinion of an abortion, for the regular uterine pains, the pre-enting bag of waters, and the enlarged uterus were enough to satisfy me of the impending issue.

I dilated the os with my finger, and in two hours and a half,

with the aid of three drachms of ergot, the mass was expelled, to the surprise of my patient; but my surprise came when I examined the *cavus belli*. It was placental upon one side, two inches and a half in diameter and about three fourths of an inch in thickness; this side was convex, and contained throughout its surface, plainly to be seen, sinuses that appeared to have been recently detached from the uterus. On the other side was the bag of waters, which had presented at my first examination; it was intact, and, when ruptured, contained about half an ounce of bloody fluid, showing not the slightest trace of a fetus, no odor, nor the least sign of putrefaction.

The lady made a good recovery, so that she attended to her usual household duties in ten days.

This patient had a missed abortion seven months ago, when she was about three months in gestation, and the fetus was macerated and absorbed. The placental attachment had been sufficient to maintain its vitality, and the bag of waters, not being ruptured, had escaped decomposition.

Cases of this kind might develop very interesting medico-legal complications.

Clinical Reports.

NEW YORK EYE AND EAR INFIRMARY.

(Aural Service of Dr. SAMUEL SEXTON.)

Neglected Otitis Media Purulenta following Vaccination, and complicated with Caries and Necrosis of the Mastoidæ; illustrating the Favorable Termination of the Disease without Active Interference.

Reported by W. A. BARTLETT, M. D., Assistant Surgeon.

The patient, a girl four years of age, was brought to the clinic on the 28th of February, 1884. Her health had always been good until two years before, when she was vaccinated. The vaccination was followed by "cow-pox gatherings" under the left arm, and in a short time by earache in the left ear. The ear soon began discharging, and has continued to run constantly until the present time. During the past six months three abscesses have formed on the left side of the head, face, and neck, one over the angle of the jaw, one in the cervical region rather posteriorly, and one—the last—came two weeks ago over the mastoid process. The patient had lost strength, was somewhat emaciated, and had had at times some febrile action. There had been no vertiginous symptoms nor facial paralysis.

Examination showed that the tissues over the mastoid process were indurated, swollen, and tender, while immediately behind the pinna and on a level with the upper margin of the concha there was a good-sized opening through which a probe, passed downward and forward, entered the antrum mastoideum. Exposed bone was detected along the sinus and in the antrum.

There was asymmetrical prominence of the auricle on the affected side. The external auditory canal, which was above the average size normally, was filled by a large polypoid mass presenting at the meatus, and bathed in an abundant, offensive, purulent discharge. The patient had some elevation of temperature and was very restless and irritable.

The first step was to remove, with forceps, a mass of granulation tissue springing from the region of the posterior wall of the canal and the mastoid antrum, and near the base of the polypus, which permitted of more thorough cleansing of the

parts with warm water by syringing as occasion required. For internal administration, calx sulphurata was ordered to be given in small doses repeated every two hours; for the pains, minute but frequently repeated doses of tincture of aconite-root were directed.

March 13th.—During the past two days the patient has been very restless and out of condition; the whole of the left side of the face and neck is somewhat swollen; there is no alteration in the condition of the post-aural region, and no marked febrile reaction. The polypus was removed with Sexton's snare, and directions were given to cleanse the canal daily and introduce powdered boric acid.

17th.—Much improvement is noticed since her last visit; the swelling about the ear has subsided, there is no pain, and the discharge from both the canal and the mastoid opening is free and copious. The post-aural opening is now dressed with a rolled cotton-wool tent saturated with tincture of calendula; insufflations of boric acid into the canal are continued.

Under this treatment decided improvement was apparent for about two weeks; after this, however, granulation tissue became much more rapidly developed, and local irritation again increased. On April 3d a polypus of considerable size, which had sprung from the base of the previous growth, was removed with the snare, and the treatment was continued as before.

It now seemed probable, from the degree of local disturbance going on, that a portion of the mastoidæ which had been the seat of caries was already sequestered, and, on April 10th, the probe detected the roughened surface of a sequestrum protruding into the external auditory canal from the direction of the antrum mastoideum. It was very firmly held, however, by the surrounding tissues, and was quite immovable.

April 17th.—Pains in the ear are again complained of, and there is some swelling of the face as well as of the tissues behind the auricle. Just within the meatus the lumen of the canal is found to be almost completely blocked up by the protruding sequestrum, and a partially detached flap of integument from the posterior wall, interfering with proper drainage.

After as much as possible of the muco-purulent secretion and caseous matter had been syringed away, it was found that the swelling of the tissues surrounding the dead bone was too great to permit of extraction by forceps without surgical interference; either the external meatus would have to be slit up freely, involving incision of the cartilage, or the auricle would require to be partially detached and turned forward—enlarging the external opening of the sinus and dividing the cartilaginous portion of the canal to some extent for this purpose—before removal could be accomplished. Rather than resort to either expedient in so young a subject, it was thought best to continue the treatment for a few days longer without interference.

24th.—The sequestrum was found to be much looser, and, although not yet fairly presenting at the meatus externus, it was firmly grasped with a Sexton's foreign-body forceps, and, after considerable traction, brought away. The ear was cleansed twice weekly, and then dressed with powdered boric acid for a fortnight after the removal of the sequestrum, when the discharge from the canal entirely ceased. The sinus behind the auricle shortly afterward closed, and the patient's physical condition was much improved. It was now found that the membrana tympani and the ossicles had entirely disappeared, and that the large cavity remaining, consisting of the tympanum, the antrum mastoideum, and the area opened up by loss of structure of the mastoidæ adjacent, was nearly everywhere covered by glistening cicatricial tissue—the transformation as regards the dermic lining having been promoted by the employment of the boric acid.

The polypoid mass removed was found, on microscopic examination by Dr. Ferguson, to be a myxo-fibroma. The sequestrum was a large one, being about three quarters of an inch in length and over a quarter of an inch in diameter at its largest portion. It was very irregular in shape, consisting for the most part of cellular mastoid substance. Before maceration it was considerably larger, but this process and the subsequent washing detached considerable friable osseous tissue.

REMARKS.—In this case the absence of facial paralysis and meningeal symptoms was noteworthy, and afforded valuable aid in arriving at the prognosis.

The calx sulphurata is believed to be exceedingly efficacious in purulent inflammations which involve the bone, especially in run-down and scrofulous subjects; it should not be discontinued too early in the treatment. One-fiftieth-of-a-grain doses, or less even, were continued throughout the active stage of the disease.

It may be said of nearly all these neglected cases where caries of the mastoidæ is present that one of the first steps to be taken is the establishment of efficient drainage from the diseased bone through the external auditory canal by the removal of polypi, granulation masses, and caseous matter wherever they are found obstructing the passage. Where this has been neglected, usually a fistulous opening through the cortex of the mastoidæ, or through the posterior wall of the external auditory canal, is formed, and drainage is thus maintained. Sooner or later, in a very considerable number of these cases, a portion of the affected bone, of greater or less size, becomes necrosed from interference with its nutrition, and a sequestrum is then detached and makes its escape in the manner above described, after which improvement usually takes place, and, indeed, very often recovery is rapid. More frequently numerous small sequestra are formed and are absorbed. In few of these cases, whether occurring in young or old, will it be found necessary to open up a new passage by trephining or drilling through the cortex of the mastoidæ, since the operation at best can but be regarded as forming an additional canal for drainage running almost parallel with the natural passage, and offering no greater facilities for that purpose. The operation, moreover, is in itself a wound in healthy structures, which may very much complicate the case, and, besides, it does not hasten the separation of sequestra, and is not more efficacious in preventing an extension of middle-ear disease to the brain than keeping the natural passage clear.

Book Notices.

Zur Kenntniss der Augenlinse und deren Untersuchungsmethoden. Von Dr. ROBINSKI, prakt. Arzt zu Berlin, etc. Berlin: Eugen Grösser, 1883. Pp. 62.

ROBINSKI, in this brochure, first criticises the different methods of investigation employed. He finds that the methods by coagulation have revealed the course of the lenticular fibers, their shape, their arrangement, and their relation to each other. He speaks highly of weak solutions of hydrochloric acid as a means of investigating the finest structural relations, especially the concentric, lamellar arrangement of the lens-tubes. For the purpose of extracting the water from the lens-tissue, Robinski regards "Müller's fluid" as the best means at our command, though it causes a shrinkage of the tissues and colors them brown. He rejects Becker's view that the lens-fibers are developed from the epithelium of the capsule. He recommends weak solutions of argentic nitrate for coloring and rendering

distinct the membranes and contours of the tubes, but, for purposes of isolation of the individual fibers, he regards weak dilutions of hydrochloric acid as still the best means at our disposal. He denies absolutely the existence of multinucleate lenticular tubes.

Medical Diagnosis, with Special Reference to Practical Medicine. A Guide to the Knowledge and Discrimination of Diseases. By J. M. DaCosta, M. D., LL. D., Professor of Practice of Medicine and of Clinical Medicine at the Jefferson Medical College, Philadelphia, etc. Illustrated with engravings on wood. Sixth edition, revised. Philadelphia: J. B. Lippincott & Co., 1884. Pp. 967. [Price, \$6.]

It is about three years since the fifth edition of this book was issued, and this fact in itself tells a tale which renders commendation unnecessary. As the work of a clear thinker and acute observer it must always be a favorite book of reference with the thinking and reading portion of the medical community. We know of no book in medical literature which is more helpful than this one to a young practitioner. Three years is too short a period of time to have produced many radical changes in the methods for the diagnosis of disease, hence we are not surprised, in turning over the leaves of this latest edition, to find it differing in few respects from its predecessor. Changes are noticeable, however, in the form of additions to the chapters upon nervous diseases, a fascinating field, and eminently so to DaCosta. We note also comment upon the recent doctrines in regard to tuberculosis. A capital drawing—the best we have seen—is given to represent Koch's *Bacillus tuberculosis*, and a guarded assent is yielded to Koch's propositions. However, pathology is not the subject of the book, and the author displays excellent judgment in confining his attention almost exclusively to the legitimate work in hand.

Legal Medicine. By CHARLES MEYMOTT TIDY, M. B., F. C. S., etc. Vol. III. New York: William Wood & Co., 1884. Pp. xxi-321. [Wood's Library of Standard Medical Authors.]

This book forms the January number of that excellent series of works—the Wood Medical Library. Its author needs no introduction, his work in the field of legal medicine having long been well known. This volume is occupied with the subjects of legitimacy and maternity, pregnancy, abortion, rape, sodomy, infanticide, drowning, strangulation, and their collaterals. A noticeable feature, perhaps the noticeable feature, of the book is the tabular arrangement of cases and judicial decisions appertaining to each subject, placed at the end of each chapter. As these are supposed to cover the field of forensic medicine (upon the given subjects, of course), their value as a means of reference will be readily appreciated.

BOOKS AND PAMPHLETS RECEIVED.

A Compend of Organic and Medical Chemistry, including Urinary Analysis and the Examination of Water and Food. By Henry Leffmann, M. D., D. D. S., Professor of Chemistry and Metallurgy in the Pennsylvania College of Dental Surgery, and of Clinical Chemistry and Hygiene in the Philadelphia Polyclinic. Philadelphia: P. Blakiston, Son & Co., 1884. [Price, \$1.]

Materia Medica and Therapeutics: an Introduction to the Rational Treatment of Disease. By J. Mitchell Bruce, M. A. Aberd., M. D. Lond., F. R. C. P., Physician and Lecturer on Materia Medica and Therapeutics, Charing Cross Hospital, etc. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xii-547.

Proceedings of the Sanitary Conference of State Boards of Health, held at New Orleans, June 2, 3, and 4, 1884.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, SEPTEMBER 13, 1884.

AN ENGLISH VIEW OF AMERICAN GYNÆCOLOGISTS.

It is but a few weeks since the "Medical Times and Gazette," of London, berated the "Medical Record," of New York, for having allowed its humor to border on levity in discussing certain novelties in practice. Having on that occasion taught by precept what should be avoided in medical journalism, it is now teaching by example what should be done. The jocose is by all means to be eschewed, and censoriousness is the proper agent to bring into play. In its issue of August 9th it publishes a review which, for downright ill-nature, we have rarely seen matched.

The volume which the reviewer has under consideration is the "Transactions of the American Gynæcological Society" for the year 1882, and at the outset he holds Dr. Emmet up to ridicule as the author of a statement, said to have been made in regard to another matter, so astonishing that, "until the subject is better understood," the position taken by Dr. Emmet in regard to his "button-hole" operation need not be considered seriously. And for thus attacking the man, instead of criticising his paper, he further justifies himself by the statement that "the bubble was pricked by Dr. Skene." Turning to Dr. Skene's published remarks on the occasion, we find that there were radical differences of opinion between him and Dr. Emmet, but that he closed with the following expressions: "Finally I may refer to the fact that the doctor reminded us of that which we all knew, namely, that his friends and those who know him best have always given him credit for honesty in all that he does and says. In this respect I desire to be among the foremost to do him honor. At the same time it must be borne in mind that honesty of purpose does not always secure accuracy of observation or soundness of judgment. Knowing this, I have dared to entertain the impression that this remarkable contribution by Dr. Emmet, while it does not embrace all that is known on the subject, will take a high position among the accepted means of diagnosis in gynæcology." And this is what the reviewer terms pricking the bubble!

He next stigmatizes Dr. Joseph Taber Johnson's paper as "also characterized by absurd exaggeration," to which Dr. Fordyce Barker's speech "will serve as the antidote." Dr. Drysdale's paper is dismissed with the remark that "it was apparent in the discussion that he has not yet convinced the profession of the diagnostic value of these bodies," meaning the "ovarian corpuscles." Of the papers contributed by Dr. Sutton and Dr. Parvin he says neither contains anything novel. Dr. Barker's paper is praised, but only, it would appear, because it reminded the American profession of a fact that, "some might think," they had almost forgotten. Mr. Thornton's paper is mentioned without any expression of opinion.

The brunt of the reviewer's renewed attack falls upon Dr. Garrigue and Dr. Thomas, both of whose papers are said to be "very unsatisfactory," the diagnosis in many of the cases being open to doubt—in Dr. Thomas's paper, "in too many of them for the paper to be of scientific value." The ball must be drawn out from the wound, then, before he will believe that the patient has been shot! He becomes moderate again in his treatment of Dr. Busey, remarking that he "simply points out what might be expected to follow; he does not adduce any evidence that these consequences actually are produced."

But when he comes to Dr. Van de Warker's paper he plies the whip mercilessly upon that gentleman and upon the editor of this journal, although the paper written by the latter was published in the preceding volume. His particular grievance is that in neither of the papers was reference made to a certain paper on the same subject, read before the Obstetrical Society of London by Dr. John Williams in 1876, with which, he says, the one by the editor of this journal is identical, "both in title and in substance." As to the title, it was "The Mechanical Action of Pessaries"—so odd a combination of words that of course it must be conceded to be the peculiar property of Dr. John Williams. As to the substance, so far as we can judge from a brief abstract of Dr. Williams's paper, published in the "Obstetrical Journal of Great Britain and Ireland," never having seen the full text, both writers argued in favor of substantially the same views, and many of the arguments employed by the two were similar, as is often the case. It is to be assumed, then, that nobody is at liberty to allude to matters that Dr. John Williams has written on, unless he proclaims the fact that Dr. Williams has so written; yet Dr. Graily Hewitt, in an edition of which the preface is dated October, 1882, has dared to do so, and so have Hart and Barbour, whose book also was published in 1882.

The papers contributed by Dr. Warren, Dr. Richardson, and Dr. Mann are briefly referred to, Dr. Richardson's being frankly praised, and then a fresh paroxysm of rancor is brought on by Dr. Baker's paper, the title of which, by a verbal error in the review, is made to appear ridiculous. "It may well have been," says this splenetic reviewer, "that the patients professed themselves well, simply to avoid further treatment." After a Partisan shot at Dr. Thomas, whose memoir of the late Professor White is said to have been written in "a somewhat induted style," our censor is kind enough to profess to see some good tendencies in the volume after all—"a less [*sic*] tendency to exaggeration, more hesitation before jumping to conclusions, some increase of scientific skepticism—in short, a little swing of the pendulum toward conservatism, caution, and moderation." That being the case, it would be interesting to know this man's opinion of the preceding volumes.

MINOR PARAGRAPHS.

THE UNITED STATES PHARMACOPŒIA.

WE lately cited a note addressed by Dr. Farquharson to the editor of the "British Medical Journal," in which that gentleman took occasion to criticise the British Pharmacopœia, and

to suggest certain changes in the forthcoming revision. Dr. T. Lauder Brunton now writes to the editor of the same journal, agreeing with Dr. Farquharson in the main, but calling attention to the desirability of taking certain steps that have already been taken in the case of our own Pharmacopœia, especially the introduction of palatable preparations. Dr. Brunton particularly mentions and commends the abstracts of the new United States Pharmacopœia, and the substitution of sugar of milk for sulphate of potassium in the formula for making Dover's powder. He also speaks in terms of approval of the simple elixir. The suspicion has been expressed that some of the unfavorable criticism that has been showered upon our new Pharmacopœia at home is the outcome of a feeling of chagrin on the part of certain persons who felt that they were not sufficiently deferred to in its preparation. Whatever foundation there may be for that suspicion, the fact that criticism apparently sustaining the suspicion has been made makes it doubly gratifying to find the book held up as in some measure an example to the profession abroad.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 9, 1884:

DISEASES.	Week ending Sept. 2.		Week ending Sept. 9.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	0	0	1	0
Typhoid Fever.....	32	15	56	16
Scarlet Fever.....	25	4	31	9
Cerebro-spinal meningitis.....	4	4	4	4
Measles.....	37	11	39	12
Diphtheria.....	25	15	17	5
Yellow Fever.....	1	1	0	0

Cholera continues its ravages in various portions of Italy. Naples, according to the press dispatches of Thursday, being the most afflicted. Some of the cases reported in other Italian towns were of refugees from Naples. A few cases are reported in Madrid and also in Marseilles. Dispatches from London state that the sanitary condition of the city is such that no apprehension is felt of the disease obtaining a foothold there.

Oleomargarine.—Agents of the Assistant Dairy Commissioner are said to be engaged in obtaining evidence against dealers in this article. It is reported that a large number of cases will be brought into court as soon as the proper evidence can be had, and that already several summonses have been issued. It will be remembered that, according to the law passed April 24, 1884, the penalty for selling oleomargarine is a fine of from \$100 to \$500, and imprisonment for from six months to a year.

Miryachit.—In discussing this disease, which was brought to the attention of our readers by Dr. W. A. Hammond, in the "Journal" for February 16th, the editors of two Neapolitan medical journals are said to have gone by and verbal polemics, and that a challenge passed from one to the other.

It was no uncommon thing a hundred years ago for English physicians to shed each other's blood with their swords, after having shed that of their patients with their lancets, and we believe that several instances of the kind have occurred in this country.

Our confrères of the Latin races are, however, probably the only ones that continue to practice phlebotomy by either method.

The Philadelphia Maternity Hospital.—According to the "Medical and Surgical Reporter," the Obstetrical Staff of the Maternity Hospital have requested the Board of Governors to appoint a female resident physician to serve in the hospital. At a recent meeting of the Governors it was unanimously resolved:

1. "That the Maternity Hospital should have a resident physician; and
2. That the resident physician must be a woman."

The Will of the late Dr. John H. Dix provides that the Perkins Institution for the Blind, at South Boston, shall receive the sum of \$10,000, and the Massachusetts Medical Benevolent Society the sum of \$2,000. Provision is also made for summer excursions for the sick or poor children of Boston.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 31, 1884, to September 6, 1884:*

BYRNE, CHARLES C., Major and Surgeon. Relieved from duty in Department of California and to report in person to the commanding general, Department of the Platte, for assignment to duty. S. O. 207, A. G. O., September 3, 1884.

TOWNS, F. L., Major and Surgeon. Relieved from duty in Department of the Columbia, and to report in person to the commanding general, Department of Texas, for assignment to duty. S. O. 207, C. S., A. G. O. Granted leave of absence for twenty-five days. S. O. 127, Department of the Columbia, August 25, 1884.

HAVARD, VALERY, Captain and Assistant Surgeon. Relieved from duty in Department of Texas, and to report in person to the commanding general, Department of the East, for assignment to duty. S. O. 207, C. S., A. G. O.

HALL, WILLIAM R., Captain and Assistant Surgeon. Relieved from duty in Department of Texas, and to report in person on October 1, 1884, to the superintendent general recruiting service in New York city, for duty at David's Island, N. Y., relieving Assistant Surgeon M. E. Taylor from duty at that station. S. O. 207, C. S., A. G. O.

HOPKINS, WILLIAM E., First Lieutenant and Assistant Surgeon. The leave of absence granted him in S. O. 67, August 7, 1884, Department of Arizona, is extended one month. S. O. 204, A. G. O., August 30, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending September 6, 1884:*

RIXEY, P. M., Passed Assistant Surgeon. Relieved from special duty at Washington, D. C., September 8th, and ordered to the Lancaster, European squadron.

OBELLY, A. S., Surgeon. Relieved from the Richmond, August 30th, and to wait orders.

DICKSON, S. H., Passed Assistant Surgeon. Relieved from Asiatic squadron, July 29th. On sick leave, August 30, 1884.

Society Meetings for the Coming Week:

MONDAY, September 15th: Medico-Chirurgical Society of German Physicians.

TUESDAY, September 16th: Medical Society of the County of Kings, N. Y.; Ogdensburg, N. Y., Medical Association; New York Academy of Medicine (Section in Theory and Practice of Medicine).

WEDNESDAY, September 17th: Medical Society of the County of Allegany, N. Y.; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark).

OBITUARY NOTES.

Dr. Robert Empie Rogers, of Philadelphia, died on Saturday last, at the age of seventy. He was born in Baltimore in 1814, and was graduated from the Medical Department of the University of Pennsylvania in 1836. For eight years he was Professor of Chemistry in the University of Pennsylvania, and on the death of his brother, J. B. Rogers, then Professor of Chemistry in the Medical Department of the University of Pennsylvania, he was appointed to that chair. In 1877 he resigned, and accepted the chair of Chemistry in Jefferson Medical College, which position he occupied until quite recently. He was a man of much note as a teacher and a lecturer, and contributed many valuable papers to scientific literature. He assisted his brother in the preparation of his edition of "Turner's Chemistry," and in 1855 he edited the American edition of "Lehman's Physiological Chemistry."

Dr. R. J. Farquharson, of Des Moines, Iowa, died on Monday last. He was formerly an Assistant Surgeon in the United States Navy, and at the time of his death he was secretary of the Iowa State Board of Health.

Dr. Riggan Buckler, of Baltimore, a well-known and highly respected practitioner of that city, died at Narragansett Pier, R. I., on Sunday, August 31st. Dr. Buckler was a native of Baltimore, and took his medical degree at the School of Medicine of the University of Maryland, having received his academical education at Harvard. He was the surgeon-general of the State of Maryland during the administrations of Governor Swann and Governor Whyte.

Proceedings of Societies.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The fifty-fourth annual meeting was held in Montreal, August 27 to 30 and September 1 and 2, 1884. The President, the Right Honorable Lord Rayleigh, in the chair. As the proceedings had for the most part no bearing upon medicine, our summary will be brief.

The Co-ordinating Centers of Kronecker.—Dr. T. WESLEY MILLS, of Montreal, read a paper on this subject, and said that the center was situated at about the junction of the upper with the lower two thirds of the heart, and toward a branch of the left coronary artery. When this was excited by an electric current or pierced with a needle, the regular beat of the ventricles ceased and a fibrillar contraction took its place, from which, in the dog, there was no recovery. It lasted generally at least five minutes, if the blood be kept oxidized; at the same time the auricles maintained the usual beat. The center was not a motor center nor an inhibitory center, but a co-ordinating center.

Its existence explained sudden death from certain forms of heart disease, from small pricks to the heart, from typhoid fever in certain cases, and death from chloroform. It also showed how dangerous it would be to apply an electric current to the heart to resuscitate one from impending death from chloroform or other such poisoning.

The anatomical relations of this center were being further investigated by its discoverer.

Dr. Mills also gave a demonstration of the center upon a dog. The animal was narcotized with morphine and placed under the influence of curari. Artificial respiration was main-

tained, the chest was opened, and the pericardium was opened and stretched back.

After a few attempts a needle was thrust through the center and the phenomenon appeared and lasted eight minutes, artificial respiration being maintained all the time. Stimulation of the vagus was seen to have no influence over it.

The Value of Nerve-Supply in the Determination of Muscular Anomalies.—Professor D. J. CUNNINGHAM, of Dublin, read a paper on this subject. He spoke of the musculus sternalis as a new muscle in man, which had no counterpart among animals. It was, according to his experience, found more frequently in females than in males; while Professor Shepard, of McGill College, had, he learned, had three cases, all in males.

Professor MOSELEY said that this subject of the anomalies of muscles had a very important function in solving many of the riddles of the evolutionary theory.

Professor STRUTHERS said that, while it was not at all impossible that new muscles were starting up within us, it was also possible that the muscles might have existed before, and not been discovered, as our predecessors did not examine things so closely as did the modern investigators in muscular anomalies.

Professor G. E. DOBSON regarded this muscle as the rudimentary vestige of a muscle found in all the lower animals, by the use of which they were enabled to draw in their heads and fore-legs when they erected their spines.

Professor MILNES MARSHALL said this muscle seemed to appear accidentally. To his mind it was not a little humiliating that it was impossible to decide whether this was a new muscle or the last vestiges of a rudimentary muscle, as held by two such authorities as Professor Dobson and Professor Cunningham.

Dr. SHEPHERD, of Montreal, had often observed this muscle, and regarded it as rudimentary in its nature.

The Growth of Children.—Dr. MINOT read a paper on this subject. He remarked that previous methods of calculating growth were incorrect. In order to ascertain correctly this value, the percentage rate must be calculated—that is to say, for any given period, the increase, calculated in percentage of the weight at the beginning of that period, and, by comparing the percentages of successive periods with one another, we get the true succession of changes in the rate.

This brings out more clearly than the study of the absolute increments has hitherto done certain irregularities. These were:

First. At seven or eight years.

Secondly. At ten or eleven years, being later for boys than for girls.

The rate thus determined also showed that the rate of growth, roughly speaking, diminished from birth onward, thus pointing to the conclusion that there was but one phase of life, that of steady decline, and that the period of increasing power was only apparent, being in reality the concealment of a steady decline. This was also proved by elaborate statistics obtained by observations upon animals.

The broad result of these studies, which were based upon elaborate statistics of many thousand measurements, was that the new individual, from the moment of its creation until its final dissolution, underwent a series of progressive changes which we designated as senescence. Senescence was, then, a fundamental phenomenon in life, which the author hoped to investigate by further and much more extensive experiments.

Numerous statistical tables were laid before the section, which had furnished the basis of the views here advanced.

Dr. D. E. Salmon's Tube for the Cultivation of Micro-organisms was exhibited and commented upon by Dr. HIRROCK.

He referred to the advantages of a solid substratum over a liquid medium in the culture of the bacteria. Dr. Koch had commended it highly, but he had employed liquid media in the culture of tubercle and common bacilli, and said that these flourished best in liquids sufficiently supplied with nutriment.

The life-history of such bacteria as live in fluids could never be traced completely without resorting to liquid cultures approximating their natural habitat in physical and chemical properties. The swarming stage of bacteria and the peculiarity of many species to collect in a membrane of the surface of liquids at a certain period of their life could not be properly exhibited upon a layer of gelatin or blood serum.

Any apparatus was desirable which would simplify the technique and reduce to a minimum the sources of error connected with the study of microscopic fungi in liquid media. Such had Dr. Salmon's tube proved to be.

The culture tube consists of a test-tube-like body or reservoir of rather heavy glass, four to five inches long, and three quarters of an inch in diameter. Over the top of this is fitted a second hollow piece, which might be called a cap. The internal surface of the cap is ground so as to fit snugly over the ground external surface of the upper end of the reservoir, thus forming a ground-joint union. This cap, about two inches and a half long, abruptly contracts near its middle into a narrow tube, with internal diameter of about three eighths of an inch. The third piece, which might be called the ventilating tube, is shaped like an inverted U, one limb being about three inches long and one inch and a half longer than the limb which fits by its ground joint over the narrow tube of the cap. The longer, free limb of the ventilating tube contains a plug of glass wool from one inch and a half to two inches long. The limbs of the ventilating tube are about one inch apart.

The culture liquid is introduced by removing the cap, which brings with it the ventilating tube. It is sterilized in the tube. The liquid is inoculated by removing the ventilating tube only. To prevent the ground joints from sticking too firmly, a little sublimated vaseline is introduced between the surfaces of the joint.

The pipette, used to introduce a drop of fluid containing bacteria, consists of an ordinary glass tube, about one fourth of an inch in diameter and two to three inches long, one end of which is drawn out into a very fine, almost capillary, tube, long enough to reach the bottom of the reservoir. A plug of glass wool occupies the other end, which is closed by a rubber bulb.

The culture fluid is thus inoculated:

The pipette is sterilized by flaming every portion of it nearly to the rubber bulb, subjecting it to a temperature of about 150° C., or, better, bringing it to a dull-red heat, taking care not to melt the capillary tube. It is hung, rubber bulb up, to prevent contact of its capillary end with anything while cooling. When sufficiently cool, the capillary portion is again drawn through the flame to destroy any particles that may have become attached meanwhile. The ventilator of the culture tube containing the bacteria to be sown is removed, and the narrow end of the cap flamed, the rubber bulb slightly compressed, and the pipette introduced, a few drops drawn up, the pipette slowly withdrawn, the cap flamed again, and the ventilator replaced. The cap of the fresh tube is now flamed, after removing the ventilator, the pipette introduced, a drop allowed to fall into the culture liquid, the pipette removed, the narrow tube of the cap again flamed, and the ventilator replaced.

The success of the work depends largely on the care and skill of the operator. The personal equation is as important in this as in other operations.

The form of the receiver might be variously modified. A flask-shaped could be used for cultures that require abundant

air. The tube-shape, however, was usually preferable. It enabled the nature of the opacity in the liquid to be readily determined, while the earliest traces of a membrane or a deposit were more readily detected than with a broad body and flat bottom. The macroscopic appearance of these features would often enable the operator to gauge the purity of the liquid.

The culture tube is a simple and neat apparatus, easily fitted, sterilized, and inoculated. It dispenses with the troublesome and dangerous expedients of disturbing cotton plugs and of tying down various air-filtering materials. It is easily cleansed, and may be used many times over. It does not readily break, has no sharp nor jagged edges, is compact, and occupies but little space in a thermostat, and there is practically no chance of contamination through the air during the process of inoculation. He had not yet seen an impure culture derived from a pure one during his experience in using these tubes. Careful investigators, among whom may be instanced Brefeld, agree that in a room properly managed a short exposure to the air is not dangerous. The utensils used, upon which particles are continually being deposited, were the chief sources of contamination.

Methods of cultivating Micro-organisms was the title of a paper by Dr. GEORGE M. STERNBERG, Washington, D. C. The schizomycetes, or bacteria, in their morphology, growth, and reproduction, presented the simplest possible conditions for the study of fundamental biological problems.

They offered special advantages for such studies because of their rapid multiplication and the facility with which pure cultures might be maintained.

The very considerable additions to our knowledge of these minute plants, which have been made during recent years by the labors of Pasteur, of Koch, and of others engaged in this field of scientific research, were largely due to improvements in technique relating to the recognition—by the use of staining reagents—and cultivation of the micro-organisms in question.

The method perfected by the writer, and described by him in a paper read at the Cincinnati meeting of the American Association for the Advancement of Science in 1881, possessed especial advantages for the cultivation of micro-organisms in fluid matter.

These advantages briefly stated were as follows:

The small flasks employed were made in the laboratory from glass tubing very expeditiously and at small expense. Each flask contained a sufficient amount of nutrient fluid and of oxygen to secure the vigorous and abundant development of any aërotic micro-organism introduced as seed. (The bacilli readily formed spores in these little flasks.)

When properly sterilized the inclosed culture fluid remained unchanged indefinitely, and the little flasks, ready for use at a moment's notice, might be packed away in drawers or boxes for years if desired, and could be conveniently transported from place to place.

The inoculation of one flask with micro-organisms contained in another, or with a drop of blood from the veins of a living animal, was effected expeditiously and with perfect security from contamination by atmospheric germs.

Small amounts of fluid might at any time be withdrawn from one of these flasks for microscopic examination without the slightest danger of introducing foreign organisms and thus destroying the purity of the culture.

Finally, these little flasks took the place of a syringe when an inoculation experiment was to be performed, the contents being forced beneath the skin or into one of the cavities of a living animal by applying heat to the bulb, thus causing the inclosed air to expand, and forcing the fluid contents through the capillary neck of the flask.

The Continuity of Protoplasm through Perforations in the Cellulose Walls of Plant-cells.—Dr. LOUIS ELSBERG, of New York, read a paper and showed specimens. He illustrated his views by reference to the structure of hyaline cartilage. Formerly cartilage was believed to consist of a homogeneous non-living basis-substance, in which were imbedded, at various distances apart, isolated living cartilage corpuscles, the so-called cartilage-cells. Now cartilage was known to be a filigree of living matter, in the meshes of which lumps of basis substance were imbedded.

Celloidine as an Imbedding Mass.—Professor William Libbey, Jr., read a paper with this title, in which he stated that celloidine was a pure form of pyroxiline, manufactured by a patent process in Germany, and used largely in photography in the place of collodion, but could be used for imbedding purposes in histology. It was prepared by dissolving one ounce of celloidine in ether (noting quantity used), and when dissolved an equal quantity of alcohol was added. Two solutions were needed, one very thin and the other decidedly thick.

The specimens were (after being properly hardened) to be soaked in absolute alcohol for an hour or two, then for the same period in strong ether, then for six hours in the thin solution, and the same time in the thick solution.

A good cork must also be soaked in some absolute alcohol, and, when ready to imbed, this cork was taken and a small quantity of the thick solution placed on one end; it was allowed to dry until it was well stiffened, then the specimen, with so much of the thick solution as would stay on it, was placed on this and allowed to dry partially, when another coating was placed over the specimen from the same solution, and this ought to be continued until the specimen had a sufficient quantity around it to hold it firmly; then it was allowed to dry, and when stiff was placed in 80 per cent. alcohol for at least twelve hours before cutting.

The sections were best cut in alcohol and preserved in it until wanted.

They could be stained as they were in the mass (as it did not stain readily) and then mounted, but they must be cleared up in oil of cedar or orangeum, etc., as the oil of cloves, usually used, dissolved the mass.

Where it was important to keep parts of the section in their relative positions, the foregoing method of procedure was best, but where it was of no importance the mass could be removed perfectly by soaking first in absolute alcohol and then in ether for a few moments, and then putting them in alcohol again or in a mixture of equal parts of alcohol, glycerine, and water, where they would keep indefinitely.

NEW YORK OBSTETRICAL SOCIETY.

Meeting of May 6, 1884.

The President, Dr. W. M. POLK, in the chair.

Papilloma of the Vagina.—Dr. W. M. CHAMBERLAIN presented a specimen, removed from the vagina of a woman about fifty-five years of age. He had seen the patient in consultation, and the attending physician had given the following account of the case, as observed through a period of several months:

"The patient was conscious of the presence of a tumor which impeded urination and yielded a watery and bloody discharge at intervals. A surgeon of some repute had seen her and pronounced the case to be one of carcinoma extending downward from the uterus and involving the posterior as well as the anterior vaginal wall to such an extent as to preclude all question of removal, and had advised that treatment should be limited to

securing tolerable comfort to the patient, the suppression of hemorrhage, disinfection, and the use of morphine as an anodyne."

A considerable hæmorrhage had occurred the day before Dr. Chamberlain was called to see her, and a mass of spongy tissue had protruded. The woman was extremely exsanguinated and hectic.

The vulva was occupied by a mass of large vegetations, and the vagina so crowded with the same that the finger was with difficulty carried through the center of the mass up to the uterus, which could not be made out as much enlarged or very firmly fixed. Examination was followed by such bleeding as to require a tampon, and to inspire a doubt as to whether any more radical procedure could be employed. On the following day, however, the tampon was removed, and the protruding part drawn down was seen to have a broad base of attachment to the superior wall of the vagina. This base was constricted by a strong elastic ligature, and a mass as large as a medium-sized lemon was cut off with the scissors. A larger amount of tissue was quickly scraped away with the finger-nails, and a tampon of glycerole of alum was rapidly inserted. After a few days the operation was repeated with the large sharp curette, and a saturated solution of chloride of zinc upon cotton was applied to the base. Thus the vagina was gradually freed until a speculum could be used. The os uteri was found small, and, though it was more or less covered with vegetations, the disease seemed to be limited to the surface. The anterior vaginal fornix still contained some of the growth, but the patient was so much improved and relieved that she was able to go to her home, out of town. Defecation and urination, which had been very difficult and painful, had become natural, and the discharge was almost suppressed.

The tumor had been carefully examined by Dr. F. Ferguson, who had made the following report:

"The tumor is composed of a fibrous stroma with abundant smooth muscle-cells, supporting epithelial cells distinctly nucleated and of large size. The arrangement of the stroma is not such as to classify the tumor readily, but it is closely allied to the variety of epithelial tumors called '*papilloma*.' From the enormous size of the papillæ of which the tumor is composed, and the bountiful supply of epithelial cells, which are in a state of active proliferation, the prognosis is rather unfavorable. If the tumor be completely removed, its tendency to return will not be so marked as that of carcinoma or sarcoma."

Meeting of May 20, 1884.

The President, Dr. W. M. POLK, in the chair.

Rupture of an Ovarian Cyst with Colloid Contents.—Dr. P. F. MUNDE presented a specimen, and gave the following history: About two months ago a patient entered his ward at Mt. Sinai Hospital with evidence of an abdominal enlargement which she first noticed last August, at which time she fell upon the right side of the abdomen and experienced sharp pain. The abdominal enlargement was diffuse, and had been steadily increasing since the accident. Her general health, although fair, was not so good as it had been. Dr. Mundé was able by a superficial examination to determine that the abdominal enlargement was not due to fluid contained within well-defined cyst-walls, and was inclined to the opinion that there had been rupture of an ovarian cyst. The patient was afterward put under chloroform, and a very thorough examination was made in the

presence of a number of gentlemen. The abdominal wall projected on either side; there was fluctuation with dullness, not changed by altering the position of the patient. It was decided to perform aspiration, but nothing was withdrawn. No bad results followed this procedure. A diagnosis was now made of rupture of a multilocular cyst with colloid contents, which had produced general chronic peritonitis and deterioration of the patient's health. In addition there was on the left side a tumor, of the size of a cocoon, which was immovable and gave indistinct fluctuation. This was supposed to be an intra-ligamentous cyst of the left ovary. Although the diagnosis was uncertain, the patient was told that the sooner an exploratory incision was made the better. After a few days' consideration she decided, inasmuch as her health was fairly good, not to have anything done. Three weeks later she returned, suffering from a great deal more pain, and in much worse general condition. The temperature had been normal, but was now 103° F. It sank, however, under large doses of quinine. On opening the peritoneal cavity, very thick colloid material was encountered, which came away in strings. The patient was turned on the side, and as much of the colloid material as possible was washed out by irrigation with corrosive-sublimate solution, 1 to 2,000. The pedicle of the ruptured cyst was tied and dropped in the usual way. All of the peritoneum below the umbilicus was intensely inflamed, being of a purple-red color; it was thickened, and covered by an exudation, particularly on the right side. Above the umbilicus the color was normal, although there was no apparent reason why the inflammation had not extended to that region. The tumor on the left side was found to be an intra-ligamentous cyst which he was in doubt about how to treat. At the suggestion of Dr. Polk he tried enucleation, which was easily accomplished, but the cyst was so fragile that on slight manipulation it ruptured. Its contents were highly fetid pus. This accident, however, had nothing to do with the death of the patient, which took place from shock about twenty-two hours after the operation. It was thought likely that the patient would have recovered had she submitted to an operation when it was first advised. The case was interesting from a diagnostic point of view, from the fact that the patient had gone as long as nine months since the rupture of the cyst had taken place, and, further, from the peculiarropy character of the material in the peritoneal cavity. The colloid matter found in the peritoneal cavity weighed thirteen pounds.

Supra-vaginal Amputation of the Uterus for Uterine Fibroid.—Dr. MUNDÉ related a second case and presented the specimen. Last autumn a physician from Harlem brought a patient to his office who was found to be suffering from a sub-peritoneal uterine fibroid. The uterus was of about its size at the sixth month of pregnancy. The chief symptom was abdominal pain. Menorrhagia was not very severe. Dr. Mundé advised against operative interference; ergot was given to control hæmorrhage, and for a time was effectual. In April a letter was received, stating that the patient suffered so much from pain that she was obliged to resort to morphine, and desired an operation. Examination showed little change in the size of the tumor; it reached to the umbilicus, and was movable and fairly hard. There seemed to be no special demand for the operation excepting severe pain. Last Friday an incision was made, reaching from the umbilicus to the symphysis pubis. The tumor was non-adherent, and was lifted out without any difficulty. The left broad ligament was tied in two places, and the ovary and tube were tied off. The right ovary was adherent too low down to admit of this treatment, and he was obliged to ligate above it, leaving the ovary and tube to be removed subsequently. This was done by ligatures, and the tube, which could not be included in the ligatures, was seared with Pague-

lin's cautery. It was intended to apply an elastic ligature around the pedicle and leave it in the abdominal cavity, but the only one at hand proved to be rotten and worthless. The pedicle was then transfixed in an oblique direction by two long pins, and an ovariectomy clamp was applied beneath. A hysterectomy clamp could not be obtained. The clamp used failed to make sufficient compression. He then applied the Maisonneuve *constrictor* beneath the clamp. It had to be applied so far down that it was impossible afterward to sew the peritoneum at all points of the circle below the wire. When the uterus was removed most of the upper part was found to be involved in the tumor. The pedicle was secured in the lower angle of the abdominal wound. On loosening the *constrictor*, with intent to remove it, blood spurted, although the large arteries in the stump were separately ligated, and it was again tightened and allowed to remain. The stump was cauterized with a saturated solution of chloride of zinc, and the wound was dusted with iodoform. No drainage-tube was used. The patient rallied well. The temperature on one occasion went up to 102° F., when the ice-coil was put on, and it came down and had not again risen above 100°. There had not been a single bad symptom during convalescence. The pedicle was now ready to fall off. There had been considerable suppuration after the fifth day, but none of the fluid entered the peritoneal cavity.

Labor at the Sixth Month complicated by a Large Cervical Fibroid.—The third case, also narrated by Dr. MUNDÉ, was that of a patient who came to the hospital two weeks ago, with a history of bleeding during her last labor, due to placenta previa. Examination revealed two tumors, a soft one extending from five inches above the pubes to the diaphragm, and a harder one extending down into the pelvis. The lower tumor could be felt through the vagina. The patient said she could not be pregnant, for she had been bleeding for several months. She was very much exsanguinated. Dr. Mundé diagnosed, in addition to the tumor, pregnancy of about the sixth month. The tumor was apparently connected with the anterior cervical wall, and filled the pelvic cavity. One of two courses might be pursued: First, to wait until term and perform the Cæsarean operation; or, second, to enucleate the tumor through the vagina, which might be done at once or at term. He thought it would not be so favorable for the patient to wait until term, because the tumor in the mean time might become considerably larger. Hence he decided to enucleate the tumor by the vagina, and fixed the day for the operation. On the morning of the appointed day the patient began to lose blood and to suffer pain, and, when he reached her, he found labor had come on, the cord and a hand protruding through the cervix. Pain was quieted by morphine, and a few hours later he proceeded to remove the tumor by enucleation with the fingers and Thomas's serrated spoon, having first made an incision five or six inches long into the capsule. No difficulty was experienced in enucleating the growth until the upper attachments were reached. It was found to weigh three pounds, and to measure eight inches in length by twenty inches and a half in circumference. A fetus of about the sixth month was then extracted without any trouble. The patient lost comparatively little blood, but the shock was quite severe. She rallied well, however, under hypodermics of whisky. The cavity of the tumor was stuffed with iodoformed gauze, which was removed on the second day. The temperature on that day went up to 102° F., but fell under the ice-coil and quinine, and to-day was normal. The patient was doing well, and doubtless would go on to perfect recovery. He had been able to find but one case on record, that of Professor Schröder, in which the patient was permitted to go on to term. In that case the tumor was then removed by vaginal enucleation, and both child and mother survived.

Dr. W. T. Lusk said he was rather surprised when he witnessed the operation, in the first case related by Dr. Mundé, to observe that the ovaries and tubes were not carried up with the tumor as in a case of pregnancy.

Dr. J. B. HUNTER thought the explanation probably lay in the fact that the ovaries and tubes had become bound down below the uterine fibroid. He referred to a case in which he removed the uterus at the cervix, and hæmorrhage was controlled perfectly by the elastic ligature.

The PRESIDENT remarked that the question how to get the peritoneum in contact with the stump below the ligature when there was great tension was an important one, and asked the gentlemen if any of them could give suggestions on that point.

Dr. HUNTER suggested transfixion with a strong silk ligature, and then tying the stump and dropping it.

Dr. MUNDÉ had seen two cases in which the pedicle was tied and dropped, and the patients died.

Dr. HUNTER remarked that his patients so treated had recovered. In one the cervix sloughed away after the operation.

The PRESIDENT remarked that in a case in which he had performed hysterectomy the cervix also sloughed away, although the patient made a good recovery.

With regard to the third case, Dr. MUNDÉ replied to a question by Dr. Hanks that the fibroid had probably been one of the fundus which had worked its way down to the cervix.

Dr. Lusk called attention to the fact that about two years ago Dr. Kessler, by invitation, presented a specimen to the society removed from a patient in whose case the result of the operation was different. Premature labor took place at about the seventh month, and, it being impossible to remove the placenta, she died of septicæmia. The tumor filled the entire lower uterine segment. In the light of the case reported this evening by Dr. MUNDÉ, it would have been well had an attempt been made to remove the tumor in the same manner. Dr. Lusk had requested Dr. Kessler to present the specimen for the purpose of drawing out an opinion as to the propriety of attempting enucleation, and Dr. Thomas and others then thought it would have been folly to attempt it. He mentioned this as an illustration of the rapid strides that had been made in uterine and abdominal surgery.

Dr. H. T. HANKS said he reported a case to the society seven or eight years ago, in which Dr. Thomas saw the patient and performed the Cesarean operation. The tumor was much smaller than the one presented by Dr. MUNDÉ, but it was within the cervix and prevented the birth of the child in the natural way. He believed that, at the meeting Dr. Lusk referred to, he asked Dr. Thomas whether, since he had devised his spoon-saw, he would not enucleate the tumor in such a case, instead of performing the Cesarean operation, and he replied that he certainly would.

Dr. MUNDÉ added that enucleation was much easier to perform in this case than it would have been in a non-pregnant woman.

Dr. HANKS reported, with regard to the case of puncture of the gravid uterus in the performance of ovariectomy, followed by miscarriage after the patient's convalescence and discharge from the hospital, that he had lately delivered the patient of a well-developed child at term.

Malignant (?) Tumor of the Pelvis.—Dr. HUNTER reported the case of a patient who came to him about two months ago with a pelvic tumor, of about the size of a pigeon's egg, situated in the region of the left ovary. About two weeks ago she was advised to enter the hospital and have the tumor removed. He at first took it to be malignant disease of the ovary. The uterus was normal and the menstrual function was not interfered with. At a careful examination, while the patient was

under the influence of ether, he felt pretty certain that the growth could not be removed, and yet he thought the patient was entitled to the benefit of the chance, for she was suffering much pain, was becoming emaciated, and the tumor was growing. On opening the abdomen, he found a tumor, of about the size of an orange, attached to the pelvic brim, and any attempt at its removal caused so much hæmorrhage that the operation was abandoned and the wound closed. The patient had done well since. He believed the case to be one of malignant growth from the bone.

Etherization by the Rectum.—Dr. HUNTER gave his experience with regard to this method of producing anesthesia. Since he first saw a notice of it by Mollière, in "*Lyon médical*," he had made use of it in as many as twenty-four or twenty-five cases, and had become quite convinced of its practicability. Dr. Weir had reported a death, in an infant eight months old, from diarrhœa, and he would not advise the production of anesthesia in this manner in such young subjects. The apparatus which he used consisted of a small glass jar, with a perforated rubber cork, through which he introduced the tube of a Davidson syringe. The bowels were emptied by an enema a few hours before the operation. The jar was placed in water of a temperature of 110° to 115° F., and soon the ether which it contained began to boil, and the vapor passed up the rubber tube into the rectum. Patients usually came under the influence of the anæsthetic in from five to eight minutes; some required ten minutes, and one was unconscious within three minutes. In but one case had it failed. At the end of twenty minutes the patient was unaffected, an ounce and a half of ether having been consumed. In one case the patient was kept under the influence of the ether administered in this manner for thirty minutes, and in another for twenty-seven minutes, neither of them experiencing any bad after-effect. In no case had any bad result followed, except that in one, in which ether was given by the rectum for five or six minutes and then the inhaler substituted, diarrhœal passages, with blood, occurred the next day, and continued for forty-eight hours, being apparently due to a hyperæmia of the rectum. His habit was to bring the patient nearly or quite under the influence of the anæsthetic administered by the rectum, and then substitute the use of Allis's inhaler. Given in this manner, only one half as much ether was usually consumed as when given altogether by the inhaler. The patient came from under the influence of the ether more quickly and felt less nausea. The sensation of dyspnoea and the stage of excitement were avoided. There was much less liability to bronchitis. He had also administered nitrous oxide by the rectum, but was not yet prepared to report upon it. He thought that in the cases reported, in which intestinal irritation followed the administration of ether by the rectum, the vapors were, perhaps, allowed to condense in the tube, and thus liquid ether was accidentally conducted into the rectum.

The PRESIDENT inquired whether the advantages alleged for this method over the use of Allis's inhaler were not also possessed by Clover's method, which was attended by but little vomiting, required but little ether, and caused comparatively little struggling, although some patients did suffer a good deal from a sense of suffocation. He had given ether by the rectum, and recognized its advantages in bringing on anæsthesia, but he thought, with Dr. Hunter, that in long operations the inhaler should afterward be substituted.

Dr. HUNTER said Clover's apparatus was cumbersome and costly.

Dr. MUNDÉ had used the Clover apparatus in numerous operations, and had been very well satisfied with it. But a very small amount of ether was consumed, and the patient came rapidly under its influence and experienced little feeling of suffo-

cation; the nausea following its use was not great, the patient came from under the influence rapidly, and, should cyanosis develop, it could easily be overcome by admitting more air. He had heard of one or two other deaths from the administration of ether by the rectum, besides the case recorded by Dr. Weir.

Reports on the Progress of Medicine.

SURGERY.

By CHARLES B. KELSEY, M. D.,

SURGEON TO ST. PAUL'S INFIRMARY FOR DISEASES OF THE RECTUM.

The Treatment of Scrofulous Cervical Glands by Excision.—Dr. J. Fagan has often advocated the excision of scrofulous cervical glands as the most radical and effectual method of treatment, and he now ("Dublin Jour. of Med. Sci.," June, 1884) relates three or four cases tending to show the good results of this method of treatment. He calls attention to a few points connected with the operation and the after-treatment which he considers worthy of notice: 1. The incision over the glands should not be made too free, but all the underlying structures should be freely divided from angle to angle of the skin-wound. When the gland is freely exposed, it should be seized with a tumor-hook and steadily, but gently, drawn through the wound. When all the affected glands are removed, any ragged shreds of cellular tissue that remain should be clipped away with the scissors, all bleeding points should be secured, and the wound well swabbed out with a strong solution of chloride of zinc. 2. Regarding drainage of the wound, he has had good results both with and without it; but, on the whole, thinks it better and safer to use either horse-hair or fine tubes. This is especially necessary where the wound is large and where there has been oozing of blood or difficulty in enucleating the glands. 3. The finest silver wire should be used in suturing the wound. It should not be passed too deep through the lips of the wound, which should be most accurately adjusted, and the sutures should be removed not later than the third day, and sooner if the slightest inflammatory blush should appear at their points of exit from the skin. The marks that follow the suppurating tracks of the sutures are far more disfiguring than the scar of the incision. 4. The most effectual way of maintaining the parts at rest during the healing of the wound is by means of a night-cap, with a pair of strings attached at either side, which are brought down and fastened in front by means of a thoracic binder, and drawn sufficiently tight to bring the head well forward upon the chest. Such a form of restraint is especially necessary in the case of children. 5. Should inflammation attack the wound, the tension should be at once relieved by removing some, if not all, of the sutures; and, if there has been no drainage, a probe should be passed into the most dependent angle of the wound and a small tube inserted.

The author holds firmly to the opinion that when disease is limited within a well-defined area, and the tissue involved is steadily, however slowly, deteriorating, its total extirpation is the only rational and effectual mode of dealing with it; and this principle is, he maintains, equally applicable whether the structure involved be gland, bone, or joint, provided anatomical considerations allow of such operative interference.

The Local Treatment of Laryngeal Tuberculosis.—Dr.

Gouguenheim ("Bull. gén. de théor.," May 30, 1884) lays down some general rules for the local treatment of tuberculosis of the larynx. He divides the treatment into: 1. The use of medicated solutions. 2. That of solid applications, or crayons. 3. That of the galvanic cautery. 4. Surgical operations—partial avulsion, tracheotomy, or extirpation of the larynx. The use of crayons he does not approve of, believing it to be more defective, less convenient, and more difficult to support than the use of fluid applications. He makes an exception of iodoform, but prefers to use even that on a small sponge with a holder. He gives the following general rules for the use of the galvanic cautery: 1. When dysphagia is due to increase in the size of the epiglottis, the weekly application of the cautery at a few points brings about a rapid and lasting benefit. 2. When dysphagia is due to swelling of the folds and of the arytenoid region, cauterization is more painful than in the former case, and is not followed by the same good results. 3. When the vestibule and superior vocal cords are involved, the cautery is well borne, but the effects are not so good as in the first case. 4. When the larynx is the seat of numerous vegetations, cauterization is absolutely indicated, and should always be preferred to avulsion. 5. When the inferior vocal cords are thickened and covered with vegetations, they may be cauterized with advantage, but only if they are movable and if there is no stenosis. 6. When the vocal cords are approximated and can not be separated, and stenosis exists either by spasm of the adductors or paralysis of the dilators, there is danger in carrying the caustics into the interior of the larynx; but this danger is less than that which follows fluid applications. As to the avulsion of vegetations, he believes it to be bad practice. It is painful, and creates wounds which may serve as points of inoculation. He much prefers the galvanic cautery. He enumerates the indications for tracheotomy as follows: 1. With a tuberculous patient, where the lesions in the lungs are not extensive, the general state is satisfactory, and the temperature nearly normal, when frequent attacks of suffocation are caused by the laryngeal stenosis. 2. The existence of extensive pulmonary disease does not contraindicate the operation if the temperature is normal and the digestive functions are undisturbed.

Intestinal Obstruction following Hernia.—Dr. Frederick Treves ("Lancet," June 7, 1884) gives a very interesting study of the forms of intestinal obstruction that may follow after hernia. In a certain proportion of all cases of complicated hernia—in a proportion by no means insignificant—certain changes are induced that may lead in the future to serious and fatal intestinal obstruction. The forms of occlusion of the bowel that may arise under these circumstances are of various kinds, and the symptoms that they induce do not appear until some time after the subsidence of the trouble in the hernia. In such cases weeks, or even years, may elapse between the reduction of a strangulated hernia or the relief of an obstructed or inflamed rupture and the appearance of symptoms of internal obstruction, although the pathology of such cases will show that these tardy symptoms depend upon morbid changes set up by the long-lapsed mischief in the hernia. A strangulated hernia that has been associated with very definite symptoms has been reduced by taxis or by operation; the reduction is complete, and the gut has been returned into the abdominal cavity entirely free from all constriction. Yet the intestinal symptoms persist, though possibly in a modified form, and the persistence may lead to death. The usual morbid conditions found in such cases are the following:

In the first place, the reduced gut may lie in the abdominal cavity simply *hors de combat*, so damaged that its coats are paralyzed, and it is quite inert. It may not be gangrenous, though it may be on the verge of death. It is an irritant to the

peritoneal nerves, it interrupts peristalsis, and, as an obstructing agent, acts as a piece of rubber tubing would if introduced in the line of the living intestine. The symptoms are often in excess of what would be expected from the condition of the gut. Perhaps laparotomy is performed and nothing abnormal is found save the listless, dead, or dying loop of gut adrift in the abdomen.

In a second class of cases the persistence of the main symptoms depends upon the development of acute peritonitis. Under such circumstances the constipation persists, the vomiting continues—although it may be less frequent and less severe—the pain increases and is more constant and diffused, there is general and extreme tenderness, all peristaltic movements cease, the paralyzed bowel is distended and meteorism appears, the temperature usually rises, and the pulse becomes more rapid and more thready.

In a third class of cases the severer symptoms that may continue after the reduction depend upon acute enteritis. This condition is usually mistaken for peritonitis with diarrhoea, or for an abiding obstruction with diarrhoeic irritation of the gut below it. In this complication, however, the abdomen is shrunken, not distended; there is comparatively little tenderness, the pain is paroxysmal rather than constant, vigorous peristaltic movements are evident, the vomiting is not severe, and there is free and often profuse purging. The pulse is usually not so thready as in peritonitis, although the temperature may be about the same.

Besides these anomalous cases there are certain definite and mechanical forms of intestinal obstruction which result from strangulated hernia. The first of these is an organic stricture of the intestine. In one form it is purely cicatricial, and is due to the contraction subsequent to the healing of a loss of substance in the mucous coat. In another form the gut is puckered and greatly narrowed by a well-localized contracting peritonitis. The former seems to appear only after a strangulated hernia; the latter may follow upon a hernia which has been simply incarcerated or inflamed. Examples of this cicatricial stricture have been met with in patients as young as twenty-six and as old as sixty, and appear to be as common after inguinal as after femoral hernia. The duration of the strangulation appears to be a factor of no moment. In one case the strangulation had lasted only thirty hours; in another, three days; yet the resulting strictures appeared to be much alike. In both, kelotomy had been performed. In all the recorded cases the patients appear to have recovered well from the hernia, and, after a varying time, during which they were free from intestinal symptoms, to have gradually shown symptoms of stricture of the small intestine. As a rule, these symptoms have appeared within six weeks or two months of the reduction of the hernia. The time, so far as the record goes, varies from twenty-six days to eight months. The symptoms and prognosis in these cases are the same as in simple stricture from other causes.

In another class of cases the herniated loop becomes fixed to the abdominal wall by adhesions after reduction. This condition is comparatively common, and has many times been the cause of fatal obstruction. It may follow strangulation, or upon the reduction of hernias which have simply been inflamed or incarcerated. It is only necessary that the reduced coil should be the seat of a slight amount of localized peritonitis. The adhesion is usually about the hernial orifice, is of limited extent, and involves the summit of the loop that has formed the rupture. Thus the gut becomes sharply bent at the adherent spot and is apt to be occluded at any time by "kinking." Moreover, a peristaltic wave passing along the bowel will be interrupted at the site of the adhesion, the fixed bowel will often be roughly dragged upon, its power of contracting will be seriously in-

paired, and it may not infrequently play the part of a paralyzed segment in the length of the gut. The contents of the bowel are apt to lodge at such a point, and, for this and other reasons, ulceration of the mucous membrane at or just above the seat of adhesion is apt to occur. The cicatrization of such an ulcer leads to stricture.

In another class of cases the two ends of the herniated loop may be fixed together by adhesions. This condition can involve only the small intestine, and is the outcome of some limited peritonitis set up in the parts of the bowel that lay within the constricting neck of the sac. A rigid loop of bowel is thus formed that will probably lie loose in the abdomen. Two varieties of loop may be formed by adhesions. In the kind just noted, the ends of the loop only are adherent and a sort of ring of bowel is formed. In the other the two bars of the loop are adherent in their entire extent, so that if the loop were to be cut across transversely the cut orifices of the gut would look like the openings of a double-barreled gun. Loops of the first-named sort may lead to a certain form of volvulus. In loops of the second sort there is great angular bending, with constant imminent risk that the bend may close the tube.

In another class of cases the adhesions between the reduced loop and the parietes may develop into a band, which, as is well known, may snare and obstruct the gut in many ways; and in still another class a part of the omentum may become adherent to the inflamed peritonæum about the hernial orifice, and an omental cord be formed which subsequently may cause mechanical obstruction.

The enumeration of these varieties of obstruction affords a precise and scientific basis to the statement that has been dimly expressed by authors, to the effect that internal obstruction appears to be unusually frequent in the subjects of rupture. Their frequency, compared with that of hernia, can not be said, however, to be very great.

A New Radical Operation for Cancer of the Rectum.—M. Pollosson ("Lyon méd.," May 18, 1884) recommends a new procedure for the radical cure of cancer of the rectum, which consists, briefly, in the performance of a double operation. The primary operation is merely the formation of an artificial anus and the complete closure of the lower end of the bowel by cutting it across at the sigmoid flexure, invaginating the extremity of the lower end and closing it with sutures. After this operation has been successful, he proposes to extirpate the cancer in the usual way. His idea is that by this method the rectum is rendered passive and inert before the extirpation, and many of the dangers attending the usual operation are thereby avoided. His article is rather a suggestion than a report of actual experience, the latter being confined to doing the first part of the operation in a single case.

Sprains and their Treatment.—M. Marc Sée ("Revue de chir.," June, 1884) goes exhaustively into the question of sprains and their treatment. He defines a sprain as consisting essentially in great distension with partial rupture of the ligaments and articular synovial membranes, causing a sanguineous exudation in the joint and its vicinity. To these lesions may be added, in severe cases, muscular rupture, laceration of tendons, ligaments, and osseous apophyses, rupture of fibrous sheaths, fracture of articular extremities, laceration of the skin, and contusion of subcutaneous tissue. He gives many suggestions as to treatment, and, among other things, lays down the following propositions regarding massage. It may be of great service in recent cases of slight sprain by relieving the pain and swelling. Generally several sittings will be necessary to produce any permanent good results, but it is impossible to determine the number in advance. In the intervals the pain and swelling return to a variable degree.

Massage generally succeeds best in the first hours after the accident. Success is more rare after the sprain has existed some days and when there is a certain degree of inflammation. It demands much patience and time from both surgeon and patient. For this reason it is often left to empirics, who abuse it. It does not always succeed, even in simple cases; it is dangerous in severe cases and those complicated with fracture. After the disappearance of the primitive symptoms of a sprain the disease is not cured. The cicatrization of ruptured parts can not take place till after a considerable time, and requires immobilization of the joint. It is, therefore, imprudent to allow the patient to walk immediately after the treatment by massage. The author himself has great confidence in the treatment by elastic compression, and lays down the general rules for its application.

Cholecystotomy.—Mr. Lawson Tait, in a note on cholecystotomy ("Brit. Med. Jour.," May 3, 1884), concludes that all the possibilities of the operation for gall-stone and distended gall-bladder were exhausted in Marion Sims's original paper; that no advance has been made by any attempt to improve upon what he recommended and performed, and that none is likely to be. He has performed the operation thirteen times, and all the patients have recovered. One old woman died of suffocative catarrh some weeks after the wound was healed, and another patient died of cancer of the liver, which was, in all probability, the cause of the distended gall-bladder, as no calculus was discovered. The remaining eleven patients are in perfect health, and the results are perfect with one exception, which exception, the author says, has taught him a great deal.

Two modifications of the plan proposed and practiced by Sims have been suggested and tried, but they are not based on good reasoning and have not been successful. The first is a proposal made by Sir Spencer Wells to open the gall-bladder, remove the calculi, and close the organ by a continuous suture without attaching it to the abdominal wound. This has been put in practice only once, and the result was fatal. A large quantity of bile was found in the peritonæum, and, though this may not have been the cause of death, it is not a condition likely to contribute toward success. But the arguments against the procedure are much stronger than the want of success in a single case. The gall-bladder is an organ subject to periodic filling and emptying, the latter process being accomplished by the contraction of its muscular walls, which contraction is much more powerful than seems generally to be supposed. It also secretes an abundant quantity of clear albuminous fluid from its mucous surface, and this fluid contains some kind of ferment, if a few rough experiments the author has made are deemed conclusive. Even if no bile enters the gall-bladder it speedily fills with this secretion and expels it; so that, if its duct were occupied by a calculus, and a wound in its base were closed by a continuous suture and not fastened to the abdominal wall, it is difficult to believe that such a wound would remain closed.

It is a matter of extreme difficulty, if not an impossibility, to be quite certain that all the stones are removed in an operation of cholecystotomy. The duct is distended by the passage of a calculus, urged forward by the pressure of the secretion of mucus by the gall-bladder itself. So long as the stone is in the cystic duct, the contents of the distended bladder consist entirely of clear mucus. After the stone has passed the mouth of the liver-duct the bile flows into the gall-bladder, its passage into the duodenum is prevented, it is reabsorbed into the system, and jaundice is produced. The cystic duct in its normal state is much smaller than the common duct, and the agonizing pain of the passage of a gall-stone seems to be limited, in great measure, to this part of its journey, for it is rare, after these severe attacks, that jaundice occurs. Should cholecystotomy be per-

formed while a stone is in the common duct, and the gall-bladder be treated as is recommended by Sir Spencer Wells, it is clear that the pressure required to force the stone into the duodenum would be much greater than that required to tear open the stitched wound in the gall-bladder; extravasation of bile into the peritonæum ever afterward would be inevitable.

Exactly the same argument is to be used with greater force against Langenbuch's proposal to remove the gall-bladder. The proposal is intrinsically absurd, for there can be no reason for removing any bladder simply because it has some stones in it. In five of the author's cases the bladder was suppurating and greatly thickened, but the removal of the stones and drainage of the bladder for a few weeks completely cured this condition. If the gall-bladder were removed at the time when a stone was lodged in the common duct, the bile must all flow, just as in the other case, into the peritonæum. The author understands that Langenbuch's proceeding has been fatal in three out of six cases where it is known to have been tried, and it would have been fatal in three of his own cases had he employed it, for in three of them stones were so situated. In two he got the stones out; in the third the stone is still there. Every drop of bile comes through the fistula and none appears to go through the intestines. The fistula is a mere pin-hole, and he has tried to close it three times, always with the result of causing an agonizing colic which lasts till the bile again forces its way through the fistula. This takes about fifty hours. He proposes to open the abdomen again, about an inch to the inner side of the gall-bladder, and crush the stone *in situ* by means of a padded forceps applied outside the duct.

As a matter of interest, the author has not the slightest evidence to lead him to believe that either quantity or quality of food, or any drugs which were used for the legitimate treatment of these cases, such as morphine, calomel, podophyllin, and rhubarb, have the slightest effect on the quantity or character of the secretion. None of the patients have suffered in any way when even the whole secretion has come through the fistula, in one case for months, save from the inconvenience of the dribbling. In one case the patient has positively gained in weight and greatly improved in health. The stools are almost milk-white, and there is not the slightest evidence of the flatulence and decomposition which are said in the text-books to be the result of biliary fistula.

Miscellany.

Infectious Diseases and Vaccination for Rabies.—"The Medical Times and Gazette" (August 23, 1884) publishes the following version of M. Pasteur's address, delivered at the International Medical Congress at Copenhagen, August 11, 1884:

GENTLEMEN: In addition to the fact that they are meetings at which the most important problems of medicine are subjected to examination, congresses also serve to indicate to posterity the chief directions of progress. Three years ago when the Congress met in London, the microbe theory in its application to the etiology of infectious diseases was still the subject of violent attack. Many who opposed themselves to advanced ideas persisted in maintaining that diseases exist "in us, from us, and by us."

One would imagine that those who hold that these diseases arise spontaneously would in London have shown themselves eager to defend this thesis, but opponents to the doctrine that the principal cause of infectious diseases is an external one did not venture to come forward, and discussion on this question was not even opened. In such an assembly as this, when all are prepared for a new triumph of truth, we see at length a way open for these men to give in to it.

For the rest, all clear-sighted men had foreseen that, as soon as one would be able to show that the spontaneous origin of microscopic life was a chimerical hypothesis, and, on the other hand, that this microscopic life had relations to organic decomposition and fermentation, theories as to the spontaneous origin of disease would cease to exist. In like manner it is from the London Congress that another important advance dates its confirmation, namely, the possibility of attenuating the different viruses, varying their infectivity, and preserving them by means of suitable cultures, and lastly, the application of this discovery to veterinary medicine. To the vaccine microbes of fowl cholera and splenic fever, one has been able to add others; and the animals that are protected against the attacks of fatal infectious diseases are now to be counted by hundreds of thousands. The violent opposition which this innovation has encountered will soon be swept away in the current of new ideas. Is the application of this new advance, then, to be confined in the future to the prevention of the diseases of animals? Besides the fact that one need never despair of a discovery and its fruitfulness, can we say that this question is already solved in its principal points? Splenic fever, for example, is common to animals and man; and we can say for certain that, if it were worth while, nothing would be simpler than to produce in man insusceptibility to this disease. The procedure which is successful in animals would be applicable without modification so to speak. It would simply depend on one's proceeding with an extraordinary degree of caution, such as the life of an ox or a sheep does not require. Instead of vaccinating with vaccine of only the second degree, one could take three or four of variable virulence, till one chose the first, weak enough not to cause the slightest symptom, but which would yet produce insusceptibility to the disease. In the case of human diseases the difficulties lie then, not in the application of the new prophylactic method, but rather in the knowledge of the physiological properties of the virus. To attenuate the virus to the proper degree, it is necessary to control our efforts by experiment; but the experiments which are allowable in animals are criminal when we have to do with man. In relation to the diseases which exclusively affect mankind, this is the chief cause of the difficulties of the investigation. Let me in the mean time remind you that the inquiry, of which we are speaking, dates, so to speak, from yesterday, that it has already been fruitful in results, and that we have a right to expect new advances when we obtain a closer acquaintance with the diseases of animals, especially those which attack both man and beast. It was the desire to penetrate further into this twofold knowledge which induced me to study rabies, in spite of the obscurity in which that disease was enveloped.

It is now four years since the study of rabies was first commenced in my laboratory, and it has been continued without any other interruption than the enforced cessations which depend on the conditions of the inquiry—conditions which are very unfavorable. The incubation of the disease is always of long duration. There are never sufficient facilities to enable one at a given moment to multiply experiments. In spite of these material hindrances, which, however, the French Government, in its care for the great scientific interests involved, has done everything in its power to remove, the experiments which we, my fellow-workers and I, have carried out, have, nevertheless, passed beyond the possibility of numbering them. To-day, gentlemen, I shall only describe the most recent results of our inquiries. Every disease, and especially such a disease as rabies, immediately makes one think of its cure, but to set one's self forthwith to search for remedies is to expose one's self to what is only too often a fruitless labor. It is in a manner to trust to accident for advance. Better is it to undertake in the first place to study the nature of the disease, its cause and development, in the distant hope of thereby discovering means of preventing it. If the problem of rabies is to-day no longer insoluble, it is to these last-named methods that we owe this advance. Thus we have proved that the virus of rabies always develops itself in the nervous system, in the brain, the spinal cord, the nerves, and the salivary glands, and never simultaneously invades every part. It may, for example, fix itself in the spinal cord, and then attack the brain; or one may find it in one or more parts of the brain and not in others.

If one kills an animal when the disease is at its height, it is often difficult to find the virus of rabies at any given point in the brain or

spinal cord, but we have fortunately discovered that, in every case in which death occurs as a natural result of the development of the disease, the uppermost portion of the spinal cord, which forms the point of transition between the cord and brain, and which one calls *the bulb*, is invariably the seat of the poison. When an animal dies of rabies (and we know that the disease invariably ends in death), it is absolutely certain that one will be able to obtain from the animal's *bulb* rabies virus, which will produce the disease by inoculation on the surface of the brain in the arachnoid cavity, after previous trephining.

If you take any street-dog you please and inoculate rabies in this manner by trephining, using as inoculating material a portion of the bulb of an animal which has died of the disease, you will invariably convey rabies. The dogs to which the disease has been communicated in this manner are to be counted by hundreds. The method has never failed. The same operation has been performed on hundreds of Guinea-pigs and on a yet greater number of rabbits, without a single failure.

These two remarkable results—the invariable presence of the virus in the bulb of animals dead of the disease and the certainty that one can communicate rabies by inoculation in the arachnoid cavity—are axioms firmly established by experiment, and are of extreme importance. Thanks to the careful application and the so to speak daily employment of these criteria, we were able to proceed with certainty in a study of such difficulty. But, however solid this experimental basis may be, it is not in itself able to show us the way to a vaccination method against rabies. In the present position of science, to presuppose the discovery of a means of preventing infectious disease by vaccination—(1) one must have at one's disposal a virus which can exist in different degrees of virulence, the weakest of which may serve as a vaccine; (2) one must have discovered a method of producing these varying degrees of virulence. Hitherto science has known only one kind of rabies, that which occurs in dogs. All hydrophobia, in dogs, men, horses, cattle, wolves, foxes, etc., comes originally from the bite of a mad dog. Rabies never arises spontaneously, either in the dog or any other animal.

None of the instances on record of rabies occurring spontaneously are really authentic; I will add that in making this assertion I do not ignore the fact that there must have been a *first* case of rabies. To come forward with this kind of objection, when it is a question of solving the inquiry which engages us, helps no one, but touches a problem which even now is still inscrutable—the very problem of life. It is like answering one who should maintain that an ovum always originates from an ovum, but, nevertheless, that the first ovum must have originated spontaneously. Science, which knows itself, sees that it benefits nobody to argue about the origin of things; it sees that such origin for the moment at least lies beyond its province.

In short, the inquiry whether the rabies virus can occur in different degrees of virulence, like the virus of fowl cholera, of splenic fever, etc., is the first question to solve in order to arrive at the prophylaxis of hydrophobia. But how does one obtain the knowledge that there are various possible degrees of virulence in the virus of fowl cholera? And to what signs does one have recourse to determine the strength of a virus which kills whenever it infects?

Does rabies present any symptoms to help us? No, these symptoms are very variable. They depend essentially on the brain or spinal cord, where the virus instantly concentrates itself and flourishes. The mildest rabies that occurs—for such does occur—may in another animal of the same species produce the most violent rabies. Can one then determine intensity by means of the duration of the incubation period? No, nothing is more variable. A mad dog bites several dogs; one of these goes mad after an interval of a month or six weeks, another after two or three months' interval, and so on. Further, nothing can be more variable than the duration of the incubation period, according to the various modes of inoculation. Does one never see hydrophobia now occur and now fail to occur after a bite or hypodermic injection under exactly similar circumstances in every other respect, while inoculation on the surface of the brain never fails, and the incubation period is in such case of proportionally short duration?

Nevertheless, it is possible to determine with sufficient certainty the strength of a rabies virus according to the duration of the incubation, but on two conditions: one must make use of intracranial inoculation, and one must bear in mind that the manner in which inoculation takes

place furnishes one of the most powerful sources of irregularity in the results, according as inoculation is by bite, by hypodermic or intravenous injection. The duration of incubation may really depend very much on the quantity of active virus, that is, the virus which reaches the nervous system without diminution or change. Notwithstanding that the quantity of virus which will produce rabies may be, so to say, infinitely small—it has been shown that, as a general rule, hydrophobia occurs in consequence of a bite, whereby the quantity of virus introduced into the body must generally be so small as to be almost indefinable—it is easy to double the length of the incubation, simply by taking a still smaller proportion of the small quantity inoculated. I will quote some examples:

On May 10, 1882, there were introduced into the popliteal vein of a dog ten drops of a fluid which had been obtained by macerating in three to four times its weight of sterilized broth a portion of the bulb from a dog which had died of rabies after being found in the streets in a mad condition.

A second dog was inoculated with a hundredth part of the quantity, and a third dog with a thousandth. The first dog was seized with rabies after an incubation period of eighteen days, the second after thirty-five days, the third remained unaffected, i. e., in this last case, and by the method of inoculation used in this experiment, a certain quantity of virus proved insufficient to produce rabies. This last dog was susceptible of rabies, as all dogs usually are, for it was again inoculated on September 3, 1882, and was seized with rabies twenty-two days later.

I take another example, which occurred in rabbits, and in which another mode of inoculation, viz., trephining, was employed: The bulb of a rabbit, which had died of rabies after inoculation with a very virulent virus, was dissolved in two or three times its bulk of sterilized broth. After it had been allowed to stand for some few seconds, two drops of the supernatant liquid were inoculated into a rabbit by trephining, another was inoculated with a fourth of that quantity, and other rabbits were subsequently inoculated with $\frac{1}{16}$, $\frac{1}{32}$, $\frac{1}{64}$, and $\frac{1}{128}$ of the same quantity respectively. All these rabbits died of rabies, and the length of incubation was eight days in the first, nine in the second, ten in the third and fourth, and twelve to sixteen days in the two last. This variation in the period of incubation was not occasioned by an attenuation of the actual virulence of the virus, such as might be produced by solution, for there was a return to the eight days' incubation period if fresh rabbits were inoculated with the virus obtained from these rabbits after death. We see from these examples that, in the case where rabies is produced by a bite or by hypodermic injection, interference with the length of the incubation period must be chiefly ascribed to the great variation which is possible in the amount, always indefinite, of inoculated poison which reaches the central nervous system.

If, then, we wish to determine the intensity of the virus from the length of the incubation period, it is unavoidably necessary to have recourse to inoculation by trephining, which is absolutely certain in its effects, and to employ larger quantities than such as would be necessary simply to produce rabies. When we operate in this way, irregularities in the length of incubation with the same virus will show a tendency to entirely disappear, because we always obtain the maximum of effect which the virus can produce, that maximum corresponding to the minimum duration of incubation.

Thus we have at length obtained a method which has enabled us to inquire into the possible existence of varying degrees of virulence, and to mutually compare them. The only secrets in this method, I repeat, are to inoculate by trephining, and to use a quantity of virus, which, although very weak, is more than sufficient to produce rabies in and by itself. This method eliminates the causes which might interfere with the duration of the incubation period, and makes it dependent exclusively on the activity of the virus, the comparative strength of which varies according to the minimum duration of incubation, which is determined by its effect.

The first application of this method was in connection with the study of rabies, and expressly in connection with attempts to discover if rabies is always one and the same, only with such differences as the varying nature of different kinds of dogs might produce. Let us, then,

take wandering mad dogs at any season you please in the same year, or in different years, and belonging to the most different varieties. Let us in each case isolate the bulb, and with the material obtained from it inoculate, by trephining, from one to two rabbits, using two drops of the fluid obtained by macerating the bulb in two or three times its bulk of sterilized liquid—all proper cleanliness being observed. Let the inoculation be performed with the help of a Pravaz's syringe, somewhat bent at the end, introducing it through the dura mater into the arachnoid space. The following will be observed: In all the rabbits, no matter what mad dog was used to inoculate them from, the incubation period will fall almost without exception between the twelfth and fifteenth days—you will never meet with an incubation period of eleven, ten, nine, or eight days, though you may sometimes meet with periods of several weeks or several months.

Rabies thus, clearly enough, possesses one poison only: its modifications, which, however, are very limited, depend simply on the known difference in the susceptibility of various kinds of dogs. But we shall now see a very marked change in the virulence of rabies virus.

Let us take after death one of the numerous rabbits which we have inoculated with the virus taken from a mad dog, and let us introduce two drops of its bulb, prepared in the way given above, into another rabbit, whose bulb again shall serve to inoculate a third rabbit, and its bulb again to inoculate a fourth, and so on. You will then observe, even from the first transmission, a diminution in the incubation period in the various rabbits. I will give an example:

In the last month of 1882, fifteen cows and one bullock died of rabies on one farm near Melun, a principal town in the Department Seine et Marne, in consequence of having been bitten on October 2d by the farm dog, which had gone mad. The head of one of the cows, which died on November 19th, was sent to the laboratory of M. Rossignol, a veterinary surgeon at Melun. Numerous experiments, performed on dogs and rabbits, showed that only the following parts were the seat of the virus, viz., the cerebrum, bulb, and cerebellum, the frontal and temporal lobes. The rabbits which were inoculated from these parts were seized with the disease on the seventeenth or eighteenth day after inoculation. With the bulb taken from one of these rabbits after death two other rabbits were inoculated, one of which was attacked by the disease on the fifteenth day, and the other on the twenty-third day after inoculation. I will observe once for all that, if we transmit rabies from one animal to another of a different species, before the virus has reached its maximum in the former, considerable irregularity is met with in the duration of the incubation period. We have here an instance of this, for the same virus in one rabbit gave an incubation period of fifteen days, and in the other one, of twenty-three days, though all the other conditions were apparently similar.

With the bulb taken from the former of these two dead rabbits, two other rabbits were inoculated. In one of these the disease appeared after an interval of ten days; in the other after an interval of fourteen days. The bulb of the former of these was in like manner used to inoculate two more rabbits, in whom the disease appeared after intervals of ten and twelve days respectively. In the fifth transmission to two rabbits, the disease appeared in both after eleven days' interval, in the same manner in the sixth transmission the disease appeared after eleven days' interval, in the seventh after twelve days' interval, in the eighth after ten days' interval, in the ninth also after ten days' interval, in the tenth after nine days, in the eleventh after eight days, in the twelfth after nine days, and so on, with variations of not more than twenty-four hours at the outside, right down to the twenty-first transmission, when rabies appeared after eight days' interval; the same interval of eight days was obtained in further transmissions, down to the fifteenth, which has recently taken place. This series of experiments, which commenced on the 19th November, 1882, is still in progress.

Allow me at this point to draw your attention to the extreme certainty and facility which characterize trephining and subsequent inoculation with rabies virus; for on every twelfth day for a period of about twenty months, a succession of rabbits have been trephined and inoculated with a rabies virus procured from a single individual, and that without any interruption in the success of the experiments.

Guinea-pigs most rapidly attain the maximum virulence peculiar to

them. In these animals the incubation period, which varies and is irregular at the beginning of successive transmissions, quickly attains a definite duration of five days. Seven or eight transmissions from Guinea-pig to Guinea-pig brings us to the maximum virulence. Moreover, both in Guinea-pigs and rabbits, one observes, according to the origin of the virus, variations in the number of transmissions required to obtain the maximum virulence. If we transmit this maximum degree in rabbits and Guinea-pigs to dogs, we obtain a virus which far surpasses in virulence that of the rabies which is commonly met with.

But I hasten to say that, whatever may be the usefulness of the discovery which I have just described, there exist and can be produced different kinds of rabies—all of which are more violent and kill more rapidly than the rabies which occurs in dogs. Scientific men overlook nothing which can be discovered in the field of science, but many whom the very thought of rabies strikes with fear look for something more than scientific curiosities. How much greater interest would man have in becoming acquainted with a rabies virus which had been attenuated in its virulence! One, then, might cherish a hope of obtaining a vaccine from the rabies virus such as we have obtained in fowl cholera, splenic fever, and even acute septicæmia. Unfortunately, the methods of procedure which were used in regard to these poisons proved themselves inapplicable in dealing with the virus of rabies. It therefore became necessary to try new and independent methods; for instance, cultivation of the rabies virus in glass.

Jenner was the first to propound the idea that the poison which used to be called "grease" in horses, but which we now more accurately describe as "horse-pox," must be attenuated in its poisonous activity, if I may use the expression, by being transmitted through cows before it could be introduced without danger into the system of man. This induced us to think it might be possible to attenuate the rabies virus by passing it through the bodies of certain animals. Many attempts were made, but in the majority of the experiments on animals the poison increased in virulence, just as in rabbits and Guinea-pigs; fortunately this was not so in the case of monkeys.

On December 6, 1883, the bulb of a dog, which was known to be mad from the fact that a child which it had bitten had died of hydrophobia, was used to inoculate a monkey by trephining. The monkey was attacked with rabies eleven days later; from the first monkey the virus was transmitted to a second one, which was also attacked with rabies after eleven days' interval. In a third monkey rabies declared itself after an interval of twenty-three days, and so on. With the bulb of each of these monkeys two rabbits were inoculated by trephining. The rabbits which were inoculated from the first monkey were seized with rabies after intervals of thirteen and sixteen days respectively; those inoculated from the second monkey after fourteen and twenty days; those from the third after twenty-six and thirty days; those from the fourth after twenty-eight days in each case; those from the fifth after twenty-seven days; and those from the sixth after thirty days.

It is thus impossible to doubt that by transmission from monkey to monkey, and from the different monkeys to rabbits, the strength of the poison is weakened in the latter just as it is weakened in the dog. A dog which was inoculated with the bulb of the fifth monkey had an incubation period of not less than fifty-eight days, although inoculation was performed by trephining. Other experiments of the same nature, which were performed on a series of monkeys, led to results of a like character. We are thus in possession of a method which enables us to attenuate the virulence of rabies. Successive transmissions from monkey to monkey produce a virus which, on being transmitted to rabbits, communicates rabies after an incubation period, the length of which gradually increases. If, on the other hand, one passes on from these rabbits to successively inoculate fresh rabbits, the rabies comes under the law of increasing virulence on transmission from rabbit to rabbit, of which I have already spoken. The application of these facts yields a method of vaccinating dogs as a protection against rabies. We take as a starting-point one of the rabbits which have been inoculated from monkeys to such a sufficient degree that hypodermic or intravenous injection does not cause death. The succeeding preventive inoculations are performed with the virus-containing bulbs of the rabbits which have been the subjects of successive transmissions of infection from rabbit to rabbit, proceeding from the first infected.

In our experiments we have as a rule employed inoculation with virus from rabbits which have died after an incubation period of four weeks, but three or four times we have renewed our preventive inoculation from the bulbs of rabbits which have been inoculated from the rabbit which served as our point of departure.

After I had brought into use this method of vaccinating dogs as a protection against rabies, and had collected a large number of dogs which were rendered insusceptible of the disease, foreseeing a more extensive application of the method, and remembering the opposition which was at first shown to Jenner's discovery, I determined to lay before a scientific commission such of my results as it was obvious must serve in the future as the basis for the vaccination of dogs for rabies.

The Under-Minister of Instruction, M. Tallières, to whom I mentioned my project, was willing to support it, and appointed MM. Béclard, Paul Bert, Bouley, Tisserand, Villemin, and Vulpian to inquire into the facts, which I had already communicated to the Academy of Sciences at its meeting on May 29th. After having chosen M. Bouley as President, and M. Villemin as Secretary, the commission at once set to work and I have the satisfaction of being able to tell you that it has quite recently presented its first report to the minister.

I will now give a brief account of the results with which the first report of this commission deals. I presented to the commission nineteen vaccinated dogs, all of which had been rendered insusceptible by preventive inoculation, and thirteen of which after vaccination had been proved by inoculation by trephining. These nineteen dogs were compared in different ways with nineteen dogs chosen from others for the purpose of the experiments. In the first place, on the 1st of June, two of the protected dogs and two of the trial dogs were inoculated by trephining under the dura mater with the bulb from a mad street-dog. On the 3d of June, one protected dog and one trial dog were bitten by a mad street-dog. On the 4th of June, the commission made the same mad dog bite another protected and another trial dog. On the 6th of June, the mad dog which had been used on the 3d and 4th of June died, and with its bulb three protected dogs and three trial dogs were inoculated by trephining. On the 10th of June, the commission had one protected dog and one trial dog bitten by a fresh mad dog from the streets. On the 16th of June, the commission had two fresh dogs, one protected and one trial dog, bitten by one of the trial dogs of the 1st of June, which had gone mad on the 14th, as a result of the trephining performed on the 1st of June. On the 19th of June, the commission had three protected and three trial dogs inoculated in one of the popliteal veins with the bulb of a mad street-dog. On the 20th of June, the commission also had ten dogs—viz., six protected and four trial dogs, chosen from several others—inoculated in a vein. On the 23th of June, it having been brought to the knowledge of the commission that a veterinary surgeon, M. Paul Simon, had a mad dog in his hospital, four dogs were brought to it—viz., two protected and two trial dogs—in order that it might bite them.

The commission on rabies has thus performed experiments on thirty-eight dogs, nineteen of which had been supplied by me as insusceptible to rabies, while the other nineteen could be made mad. Those of the dogs which have not died as a result of the experiments are under observation, and will be kept under it for a long time. As to the present condition of the dogs which have been the subject of inquiry, the commission report that, in the case of the nineteen trial dogs, of six which were bitten rabies occurred in three, of seven which were inoculated in a vein it occurred in five, and of five which were inoculated by trephining it occurred in all, while not a single sign of rabies has shown itself in any of the nineteen vaccinated dogs.

During the course of the inquiry one of the protected dogs died on the 13th of July from a sanguineous diarrhoea, which first declared itself in the early days of that month. In order to determine whether rabies had any share in its death, three rabbits and one Guinea-pig were at once inoculated with its bulb by trephining. All of these four animals are still in the best of health, which is a certain proof that the dog did not die of rabies, but of a common disease.

The next report of the commission will contain information as to the insusceptibility to rabies of twenty dogs which have been vaccinated by the commission itself.

DRYNESS AND ELEVATION
THE MOST IMPORTANT ELEMENTS IN THE
CLIMATIC TREATMENT OF PHTHISIS.

By CHARLES DENISON, A. M., M. D.,

DENVER, COL.

(Concluded from page 288.)

1. *Temperature.*

Temperature is the greatest of all the producers of dryness. The relative humidity, varying from 30 per cent. or less of saturation up to complete saturation, is of small account compared with the capacity of the air to hold moistures under as widely varying degrees of temperature. A glance at the first two columns of Table I shows this capacity to be about one half a grain at zero and nearly twenty grains at 100° F. Thus it is seen that a relative humidity of 40 per cent.—an unusual occurrence at sea-level—in a very warm climate really indicates several times more moisture than the atmosphere can hold at saturation—an unusual occurrence in the Rocky Mountains—in a very cold climate.

2. *Altitude.*

It is when the conditions which prevail in the elevated interior of our continent are added to the influence of temperature that the extreme dryness is produced which is characteristic of that section.

Altitude is a very important agent in the production of dryness. The removal of the thick stratum of the, so to speak, vaporized atmosphere, such as covers the sea and lowlands, which intercepts the sun's rays, retains heat, obstructs radiation, and produces equability, is here to be noted. There are many conditions ushered in by altitude which have a favorable drying influence on the atmosphere. Prominent among them all is its cooling influence on temperature. Authorities differ, but it is safe to say there is an average lowering of temperature 3° F. for each ascent of one thousand feet in elevation. These changes are not always uniform for all the strata of the atmosphere, but are nearly so, if we except local and physical conditions which are favorable or detrimental, as the case may be, to certain localities.*

This cooling of the temperature, as we have already mentioned, lessens the capacity of the air to contain moisture, while still other conditions, which elevation insures, lessen the relative amount of moisture the air contains. These conditions are such as the character of the soil, the configuration of the earth's surface, and—what I have not seen noted by others—the expansibility of the air due to the diminution in atmospheric pressure. According to Glaisher's table, a given space of air at a given temperature will hold a given amount of moisture at saturation. If these tables are alike applicable to the atmosphere a mile above sea-level, then there is *relatively*, as well as *actually*,

* M. Glaisher, in the records of his balloon ascension, gave the fall in temperature as 5° F. for each of the first four inches of barometric fall; then 4° for each of the next eight, and 4.5° each for the next and last three inches fall.

much less moisture in the given space at the elevated station than at sea-level, temperature remaining the same, because some of all the constituents of the air, moisture included, have been driven outside the given space by the expanding influence of lessened atmospheric pressure. Is it not fair, then, to assume that actual dryness is doubly assured by elevation through the cooling process and by the diffusive effect of the expanding air?

3. *Latitude.*

Latitude insures dryness and variability—or their opposites, moisture and equability—as the distance from the equator is increased or diminished. This law is varied by the amount and character of the land exposed above the sea, by mountain ranges, and by air and ocean currents. It operates, so far as it goes, like altitude, through the effect of changed temperature, the qualities of moisture and equability following the increased heat toward the tropics, until under the equator greatly elevated localities begin to partake of the equability and moist characteristics of the lowlands in the north temperate zone.

4. *The Seasons.*

The seasons are, of course, synonymous with temperature in their effect on the humidity of the air. But there is a law to be drawn from the times of the sun's greatest and least influence upon the land and water making up the earth's surface which confines equability to the warm seacoast, and forbids her association with the desirable dryness that is found in the elevated interior of our continent. Land both absorbs and radiates the sun's heat more than water. The contrasts, then, for both the diurnal and seasonal fluctuations of temperature are exaggerated by land and lessened by the ocean. Land is, then, the *enemy* of equability and a *producer* of variability. Notice Guyot's isothermal lines, for winter and for summer, drawn around the globe (Johnson's "Encyclopædia," p. 981, vol. i). Those seasonal temperature lines which, but for ocean currents, would have run nearly parallel on the broad sea, immediately diverge on striking a continent, the summer isotherms running far to the north, especially in elevated sections, and those of winter bending toward the equator. What better evidence is needed that equability is the companion of the moisture-producing sea, while variability is the necessary consequence of inland elevations?

5. *Distance from the Ocean.*

Distance from bodies of water and absence of forests are alike favorable to dryness. It is in no small degree due to these characteristics that the extensive plateaux in Wyoming, Colorado, and New Mexico present a uniform dryness of atmosphere not found in the high altitudes of Switzerland (Davos, St. Moritz, etc.), though the latter are in great esteem among foreign physicians. The distilling process constantly going on over the sea and all bodies of water to supply the atmosphere with vapor, which returns to the thirsty land in rain, is wanting in the elevated interior of our continent. Not only is this so, but the more the forests are absent or

cleared away, the more the earth is not clothed with thick grasses and undergrowth (notice the short buffalo-grass, the dry cacti, and the sage-brush of Western elevations), so much the more is the quick draining of the land favored and any approach to the water-distillation of the ocean rendered impossible.

6. Mountain Ranges.

The upward projecting faces of the mountains intercept air-currents which come from a distance over damp, warm valleys, or perhaps an equatorial sea. The atmosphere, charged with 70 to 80 per cent. of invisible vapor, where those currents originated, is quickly raised to saturation by the cooling of the air in its onward, upward, and perhaps northward flight, and, as a result, the moisture is precipitated in rain or snow on the mountain-sides. This process is again repeated on the next interior and higher range of mountains, and again on the next, if there are more, until that occurs which is constantly to be noted in eastern Colorado—i. e., the southwestern winds, having thus traversed many mountain ranges, are the driest winds that reach that section, while the little rain that falls in the northeastern part of the State is brought by opposite currents from the north Missouri valley. Southward and into New Mexico, however, the same general reasoning holds good, the mountain ranges to the northwest furnishing the dry winds, and the Gulf of Mexico, on the south and southeast, those bringing rain. We find here an explanation of the peculiarity brought out by the rating of places in the extreme northwest section of the United States according to the climatic rule for dryness—i. e., summer very dry, but winter and spring very damp. The low temperature of the cold seasons is like the elevated mountain-sides. The warm equatorial or ocean winds are lowered in temperature and become rain-bearing, or approximately so, as they sweep over that northwestern land.

7. Absorbing Power of the Earth.

The earth has an absorbing power of greater or less degree. The less is seen in saturated and closely packed clay, in the mud of spring-time, and in swampy localities, while, on the other hand, the greater absorption resembles that of thirsty chemicals, such as porous dry sand and light, friable, loose earth. So much does dryness of the air depend upon this absorbing quality of the ground that it is impossible to find a very dry atmosphere where the characteristics of the soil are generally those having the least absorbing power. With this idea in mind, please compare, in the second column of Table II, already given, the fifteen driest with the fifteen moistest stations. Notice how very generally the highest relative humidities belong to the places of extreme moisture located in low sections with saturated or clay subsoil, while the lowest relative humidities are very decidedly in places of extreme dryness, all of which are known to be high and representative localities of large areas of dry sand, disintegrated rocks, and gravel, variously mixed. From northern Wyoming, western Nebraska, Kansas, and Texas, west and southwest, even to the Pacific borders of southern California, the latter characteristics abound, promoting the

rapid absorption of atmospheric moisture and the quick disappearance of rain and snow.

8. Radiation.

The experience of some of my patients who have resided among the foot-hills and in the cañons along the lower eastern borders of the Rocky Mountains has led to the belief that there was a somewhat increased curative influence there, more than was due to the dryness of the plains. I think we can attribute it to two sources: the greater facility and incentive for the very healthful climbing exercise, and to the increased radiation afforded by the many upturned faces of the broken-up rocks in sections destitute of the grasses and foliage of the level plains. This influence in many valleys, sheltered from strong inclement winds, tends each day during the long cold season to warm and dry the atmosphere in a manner unknown to the open country. It is here to be remarked that, through the effect of increased radiation, heat is necessarily not easily held stationary in the atmosphere, and thus the variability is explained which is remarkable in such exceptionally dry places.

9. Diathermancy of the Air.

The clearness of the air is a potential factor in producing the dryness of a given section. This is the case on the "backbone of the American continent," as the Rocky Mountain region is sometimes termed. There the much better results obtained by invalids occupying rooms on the south than on the north side of a house, the snow rapidly disappearing on the sunny side of a building while water is freezing in the shade, and the intense perception of the heating qualities of the sun's rays when falling on the bare surface of the human body—all these point to a peculiar condition of the stratum of air through which the sun shines.

This diathermancy, or the increased facility with which radiant heat is transmitted, I sought to determine by noting the influence, at various elevations, of the sun's rays upon ordinary metallic thermometers, as compared with the temperatures in the shade.* A sufficient number of observations were taken, excluding, as nearly as possible, the interference of any clouds, winds, or artificial heat, to approximately establish the following as the rule of increasing diathermancy of the air: For each thousand feet rise in elevation there are about four degrees greater difference between the temperatures in the sun and in the shade on perfectly clear days at 2 P. M., as recorded by the black metallic-backed thermometers, other influences than those of shade and sun being excluded.

When applied to sections a mile above the sea, like that east of the Rocky Mountain foot-hills, the estimation of this influence of the clearness of the air is very interesting with reference to increased solar and terrestrial radiation, and, consequently, as already shown, to the dryness of the air. "The solar radiation is rapid, and soon after sunrise the temperature rises because of the slight resistance which the rarefied and dry air offers to the sun's rays, while after

* "The Rocky Mountain Health Resorts." See chapter on the "Diathermancy of the Air," p. 66, second edition, 1882. Boston: Houghton, Mifflin & Co.

sunset the terrestrial radiation is also rapid, because there is no moist envelope shrouding the face of the earth to prevent the natural cooling of the dry ground.*

The therapeutic value of light and sunshine is, unfortunately, too little understood or appreciated. Lombard† states that *light stimulates and darkness impedes respiration*, and, through respiration, of course, animal heat and muscular activity. Moleschott proved this fact by experiments upon himself; and the scientists Bidder and Schmidt, noticing that animals, at rest, produced more carbonic acid in the day-time than at night, equalized the amount by depriving them of the influence of light. The experience of consumptives, some sixteen in all, seeking reputed benefit from the *equable* temperature of the Mammoth Cave in Kentucky, resulted, of course, in failure, five dying within a short time and others being injured—a result due, undoubtedly, to the darkness and dampness combined.

10. Sunshine.

It is no wonder that the sun has been the deity of worshipping millions, where his Creator has been unrecognized, for the source of life and means of growth of every living thing is the orb that ushers in the light and warmth of day. Almost equal to the combined evidence of both absolute and relative humidity—as to the dryness and desirability of a given climate—would be an exact statement of the proportionate time the sun shines over the country. Of course, the open and elevated sections would have proportionately more sunshine than towns secluded in valleys, and this would be in addition to that due to the more cloudless skies of the elevated interior.

No such records for the United States have been taken, however, and the nearest approximation to accuracy now obtainable are the cloudiness observations as made by the Signal Service and reported by telegraph at 7 A. M., 3 P. M., and 11 P. M., Washington time. These observations, averaged for seasons and graphically illustrated to represent the whole United States, I have been desirous of obtaining for several years past. I am pleased to be able to present them now as compiled by the Signal Service officers.‡

* In connection with the diathermancy observations mentioned, I pointed out the criticism to which the Signal Service methods of computing mean temperatures were liable. Particular reference was made to the rapid cooling of the air in the elevated sections named. The Signal Service, to compute their means of temperature, used to combine twice their cold 9 P. M. observations with the almost equally cold 7 A. M. and the one warm 2 P. M. observation, and divide the sum of these by four to obtain the average, a process manifestly misleading when one considers the ten warm hours which in Colorado prevail from 8 A. M. to 6 P. M. It is during these hours that being out of doors in a cold and rarefied atmosphere is especially enjoyable, and they are in strong contrast to those hours which used to make up three fourths of the day in the estimation of the Signal Service Bureau. The present method, however, according to which the foregoing data were obtained, is much nearer just to all sections. It consists in combining the 7 A. M., 3 and 11 P. M. observations, and dividing by three to obtain the daily records.

† *Traité de climatologie médicale*, par le Dr. H. G. Lombard, de Genève, Paris, 1877, p. 221, t. i.

‡ These charts, both for cloudiness (I, II, III, IV) and absolute humidity (V, VI, VII, VIII), were prepared by the Signal Service Bureau in response to a request presented by the author to the Colorado State

The four charts shown represent the mean cloudiness in tenths, zero being no clouds, and ten entire cloudiness.

Chart I, for spring, shows the upper section of the United States, from Washington Territory to Maine, and again from Maine along the Atlantic coast to North Carolina, also from Michigan south to Texas—a large section, where over five tenths of the observations showed cloudiness, while South Carolina, Georgia, Florida, and the entire southwest, from Wyoming to western Texas and southern California, are below five tenths cloudy; much of this region is far below that, the sections represented by Yuma and El Paso being less than two tenths.

Chart II, for summer, shows the much more equal distribution of clouds over the country than for any other season. In general, the eastern third of the United States, excepting the New England States and the Atlantic coast above North Carolina, are above five tenths, and nearly the whole of the western two thirds of the country below that. The eastern portion of California (Sacramento, Visalia, and the Death Valley) is even less than one tenth cloudy.

Chart III, for autumn, is, like spring, a fairer representation of the cloudiness for the whole year than either winter or summer, and yet there is a slight shifting of the most cloudy sections. Here the region of the lakes, the north Atlantic coast, and the northwest corner of the United States bear off the palm for cloudiness, being over five tenths; while the southwest is remarkable for the absence of clouds—Denver, El Paso, and Yuma being below 20 per cent. cloudy.

Chart IV, for winter, is characterized by the marked preponderance of cloudiness in two directions—the Mississippi and Ohio Valleys—where the percentage is above six, and the lake region, where it is above seven tenths, while in Washington Territory and Oregon the average is above six tenths cloudy. This is in perfect accord with the rating of all stations by the rule, as before explained. Central Colorado (Denver) and much of New Mexico, Arizona, and southern California show the least cloudiness—namely, two to three tenths.

11. Absolute Humidity.

A small number of grains of moisture to the cubic foot of air for a given temperature is the most exact measure of the dryness of a given locality that we can obtain from any one attribute of the atmosphere. If isotherms were run—as they should be—through the four accompanying charts, which give for seasons the grains of vapor to the cubic foot of air all over the United States, the variation of each locality from saturation could easily be determined by the aid of the preceding table of Guyot (Table I, column 2). The actual and relative dryness would thus be apparent for each separate place investigated. However, these charts (Charts V, VI, VII, VIII) show, in striking contrast, the much greater amounts, by accurate measurements, of moisture that the atmosphere contains in some portion of the United States than in others. For instance, for spring, summer, and

Medical Society at the session of 1883. A similar resolution, passed by the section on Practice of Medicine of the American Medical Association four years ago, resulted in nothing, for lack of the necessary interest on the part of the publishing committee.

autumn (Charts V, VI, VII), much of Wyoming, Colorado, New Mexico, Arizona, and Nevada contain one fourth in spring, one third in summer, and about one fifth in autumn, as much atmospheric vapor as Florida and the gulf coast in Texas, while in winter the greatly lessened capacity of the air to hold moisture at low temperatures is exemplified in the frozen atmosphere of the northern interior section, where there is not one tenth the absolute humidity there is on the gulf coast.

12. Relative Humidity.

There are but a few exceptions to the statement that the combined forces which produce atmospheric dryness also give a low rate of relative humidity. Saturation of the air with invisible vapor being 100 per cent., the relative per cent. actually found in the air is usually in harmony with the condition of dryness or moisture of a locality, 67 per cent. of saturation being about the mean for the United States.

But the few exceptions that there are to the above statement are sufficient to render relative humidity alone an unsafe guide as to the question of dryness. I think I have given this factor its full proportion of rating power in the rule for dryness by combining it—with its usually higher percentages—with both cloudiness and absolute humidity.

TABLE IV.

Places of Greatest and Least Relative Humidities, by Season and the Year 1883.

	Spring.	Summer.	Autumn.	Winter.	Average.
GREATEST.					
Mt. Washington, New Hampshire.....	91.9	91.5	88.6	86.5	89.6

Denver, Colorado.....	55.8	50.8	50.1	57.4	53.8
Average.....	45.2	42.8	48.8	55.2	48.3

Relative humidity is somewhat fickle, because it is greatly influenced by purely local causes. For instance, currents of air which are absolutely dry, when rising to a higher

and inland point, become relatively moist and different from the undisturbed atmosphere of the locality or its immediate neighborhood. The high relative humidities of Mount Washington, Pike's Peak, and partly so of Deadwood, Dakota, Cape Mendocino, and San Francisco, Cal., in the foregoing table (Table IV), which gives the fifteen greatest and fifteen least mean relative humidities in the United States, are thus explained.

13. Dryness Indicated by Variability.

Hitherto it has not been customary for climatologists to see any good in variability.* They have rather preferred to champion its opposite—equability. It does not seem to have occurred to them that the qualities which they praised, such as clearness and purity of atmosphere—especially its freedom, with increasing elevation, from disease germs and the evidences of the lower forms of life which thrive on warmth, moisture, and equability—are largely due to the great seasonal and other ranges of temperature and to the nightly chilling or perhaps freezing of the atmosphere. It is not necessary to introduce any argument of a speculative

* If it is attempted to make any exception in favor of such places as Cape Mendocino or other California towns bordering on the ocean, let it be understood that, though the ground is dry and parched, the equability is due to a continuous moist wind which blows landward from the Pacific Ocean and does not part with its equable characteristics until, rising on the interior ranges of mountains, it has lost its moisture and become dry and therefore variable.

character. Statistics prove, beyond the possibility of successful contradiction, that variability is a distinguishing attribute of really dry places—whether elevated above sea-level or not—and that equability is, as a rule, characteristic of a uniformly damp atmosphere.

The foregoing table, giving fifteen places each of the greatest and least mean daily ranges of temperature for seasons and the year from all the Signal Service stations in the United States, is a sufficient proof in itself of the general statement here made. So also is the record of the mean daily and mean monthly ranges of the twenty-five dry and the twenty-five moist localities (for the former see Table II, and for the latter see Table VI, giving monthly ranges with average precipitation added), and chosen without any reference to this particular evidence. For the four divisions of climate the total mean daily and monthly ranges, averaged for the year, are as follows:

	Means of Daily Ranges.	Means of Monthly Ranges.
1. Extreme dryness.....	36°-51° F.	53°-65°
2. Moderate dryness.....	20°-63°	49°-38°
3. Moderate moisture.....	17°-09°	45°-48°
4. Extreme moisture.....	13°-61°	41°-55°

The places of extreme dryness, according to the rating rule, are more than twice as variable in daily temperature than those of extreme moisture, while the monthly means regularly decrease in variability at the rate of about 4° for each division of climate from the extreme of dryness to the extreme of moisture.*

Physical Effects of Dryness.

There are so many conditions which on the one hand vary the character of the air breathed, and on the other the respiratory activity, that any opinion of the effect of dryness which we can formulate will be only approximate. The chief effect, of course, is upon pulmonary transpiration, and enough can be gleaned from the experiments of Valentin, Sanctorius, Lavoisier, Seguin, Dalton, and others, to understand that this process is a very important part of our physiology; yet all of these investigators miss the mark we

* In making these computations, one can not help noticing the equalizing influence of the summer temperatures, an effect increasingly apparent as the extreme of moisture is approached. This is in perfect harmony with the preference to be given to a cool or cold temperature when desirable dryness is to be sought for a given invalid.

are now aiming at, which is to determine the amount of moisture exhaled (above that inhaled) in a dry *more* than in a damp atmosphere. They may all agree with Valentin that the amount exhaled in each twenty-four hours varies from 6,000 to 12,000 grains of vapor, according to the respiratory capacity, etc., in a man not severely exercising. I have not, however, been able to find any comparisons based upon the hygrometric condition of the air breathed.

Temperature and altitude, with distance from the sea, are such powerful agents in producing dryness that it is well for us to divide our own inquiry—namely, the increased pulmonary transpiration in (1) warm dry, and (2) in cold dry air.

First in warm dry as compared with warm moist air. Let us choose Yuma, Arizona, and Jacksonville, Fla., for the autumn of 1883, as they both had the same mean temperature for that season—71°3'. Dalton assumes, in his calculations, that the air passes from the lungs in a state of saturation, and Draper puts the dew-point of expired air at 94°. Let us assume that the expired breath brought down to 94° is saturated with vapor; that an ordinary-sized man breathes eighteen times a minute (Queletec) and expires twenty cubic inches at each breath when at rest (Hutchinson, Flint Jr., and others); that he breathes the same amount of air in Jacksonville as in Yuma, and that the loss by breathing of $\frac{1}{10}$ to $\frac{1}{60}$ in volume (Davy and Cuvier) is made up by the expansion of the air in the lungs being raised from 71°3' to the heat of the body. We have, then, the following calculation:

AUTUMN, 1883.	YUMA.	JACKSONVILLE.
Mean temperature.....	71°3'	71°3'
Weight of vapor with air saturated (Glaisher).....	8·33 grains. 428	8·33 grains. 774
Mean relative humidity.....		
Air breathed in 24 hours.....	300 cubic feet.	300 cubic feet.
Vapor inhaled in 24 hours.....	1,070 grains.	1,934 grains.
Vapor exhaled in 24 hours, with dew-point at 94°.....	5,007 grains.	5,007 grains.
Vapor exhaled more than inhaled in 24 hours.....	3,937 grains.	3,073 grains.

Excess for Yuma over Jacksonville, 864 grains a day.

The amount of air breathed ought to be increased one fifth, on account of the increase of breathing due to ordinary exercise. We thus have about $2\frac{1}{2}$ ounces, or $\frac{2}{5}$ of a gill, more moisture exhaled in Yuma than in Jacksonville each day.

Crawford has shown by experiments that the exhalation of carbonic acid from the lungs is much greater in low than in high temperatures, and Draper says twice as much carbonic acid is liberated with a temperature of 68° as at 106°, while Lehmann* has likewise shown that exhalation of carbonic acid is greater in a moist than a dry atmosphere, temperature remaining the same.† Therefore we are compelled, in order to favor the exhalation of carbonic acid, to take our dryness with the favorable cold temperature. This leads

* Lehmann, "Physiological Chemistry," Philadelphia, 1855, vol. ii, p. 414.

† Dr. Lombard, of Geneva, in a paper presented to the International Congress of Hygiene (September, 1882), concludes that "in the altitudes the digestion, the muscular exercise, and the lowering of the temperature increase and accelerate the exhalation of carbonic acid."

us to the more important comparison—that between warm moist and cold dry air. It is here that altitude, distance from the sea, etc., come in, as they produce both the coldness and the dryness we need.*

Let us choose Denver and Jacksonville for the autumn of 1883, and give Denver the benefit of one fifth greater amount of air breathed, the air there being about one fifth rarefied. This will account for the deeper and more frequent respirations† and the corresponding greater activity of the heart in ordinary life, but not for the greater increase under severe exercise, like climbing hills, etc.

We will assume as breathing in both places a good-sized man, thirty years old, breathing eighteen times a minute at sea-level, and expiring an average of thirty cubic inches (Dr. Gréhaud), ordinary exercise included:

AUTUMN, 1883.	DENVER.	JACKSONVILLE.
Mean temperature.....	50·4°	71°3'
Weight at saturation for given temperature grains in a cubic foot..	4·44	8·33
Mean relative humidity.....	·501	·774
Amount of air breathed in 24 hours {	933,120 cub. in., or 540 cub. ft.	777,600 cub. in., or 450 cub. ft.
Vapor inhaled in 24 hours.....	1,461 grains.	2,901 grains.
Vapor exhaled in 24 hours at 94° dew-point.....	9,013 grains.	7,510 grains.
Vapor exhaled above that inhaled in 24 hours.....	7,552 grains.	4,599 grains.

Denver's excess in transpiration, 2,453 grains, or $5\frac{1}{2}$ ounces, or $1\frac{1}{2}$ gills.

This would amount to over six ounces, or one and a half gill, if the considerable expansion of the air in being raised in the lungs from 50° to 98° is accounted for at Denver.

Denver and Cedar Keys, compared in the same way for last winter, results in 2,935 grains, or $1\frac{1}{2}$ gills more moisture being exhaled from the lungs in Denver than in Cedar Keys. Now, I wish to ask, Does it not stand to reason that this transpiration of surplus vapor is a most admirable vehicle for carrying away effete matter, wasted tissue, and the germs of disease (bacilli)? Is it a wonder that thirst for fluids, an appetite for food, as well as the ability to digest it, are greatly increased in all those who, coming to the elevated interior of our continent, can stand the strain without disturbance of the nervous system?

If the foregoing conclusions are reasonable, can you not imagine the decided influence, especially upon the respiratory activity and function, caused by climbing the hills and mountain-sides in Colorado, when one at sea-level, walking at the rate of three miles an hour, consumes three times as much air as when at rest (Dr. Edward Smith)?‡

* I have in mind the excellent results obtained in a year's sojourn in Colorado by a patient of mine, the daughter of a London physician, who had wintered in Algiers, a very warm dry place, and spent two winters at Davos, Switzerland, but is now decidedly confirmed in favor of Colorado as a sanitarium. The experience of other patients, who tried southern California and then settled in Colorado, also strengthens this preference to be given to dryness with a cool temperature.

† This allowance is equal to three respirations and three to five more cubic inches of air inhaled each minute.

‡ The uniformly increased thoracic capacity observed in young persons after taking up a residence in elevated regions, even to the production of local or general emphysema in some invalids who have had phthisis arrested there (Dr. C. Theo. Williams, London), is likewise explained by these considerations.

In fine, do you not think there was good ground for Dr. John Parkin's statement in the preface to the second edition of his brochure on "Climate and Phthisis"?*

"As so much ignorance exists in England on the subject of climate, even with medical men, and as so many invalids are annually subjected to what one writer has termed *medical transportation*, I am induced to publish another edition of this work in order to warn, once more, consumptive patients and others of the dangers attendant upon a sojourn in the south of Europe, and other warm climates more especially."

[We have been obliged to leave out the eight humidity and cloudiness charts intended to accompany this paper, because their preparation would have delayed its publication.]

ELECTROLYSIS IN THE TREATMENT OF ORGANIC STRICTURE OF THE URETHRA.

BY WILLIAM H. DUKEMAN, M.D.,
OLEAN, N. Y.

Of the various methods in vogue for the successful treatment of organic strictures of the urethra, electrolysis excels all others. This method has been before the profession for only a few years, and, to all who have given the operation a fair, impartial, and careful test, success has invariably been their crown of reward.

The operation by electrolysis is simple in its *modus operandi*, requiring no assistants and no anæsthetic. There is no hæmorrhage, and no pain inflicted, neither during nor after the operation. It does not debar the patient from his daily vocations. Life is not endangered, and the result is a permanent cure, and therefore the patient is not required to pass a sound every few weeks or months to prevent a recurrence of the stricture.

Where can we find another method of operation that can claim such safety, simplicity, and that glorious result, a permanent cure? I answer, Nowhere. Then why is this operation not more generally employed? Simply because it has not been thoroughly tested by those whose words speak authoritatively. In surgery it appears that if no artistic skill is required and no heroic measures are employed for the performance of an operation, little is said about it. In this operation no skill is required beyond that of passing a bougie successfully into the bladder. The work of the operation is all done by the galvanic battery. The operator merely introduces the bougie to the seat of the stricture and gently holds it there with the point in the proper direction, and the electricity slowly dissolves the stricture. He must only have patience to wait for the passage of the instrument through the stricture, just as he waits patiently when he places a fever thermometer in the axilla or under the tongue. Ten minutes will register that which he seeks for. In a little longer time, spent similarly after the bougie is introduced and working on the stricture by electrolysis, he will have achieved great results. An impermeable stricture will have been dissolved and permeated,

and the patient, who for months or years has not urinated *per vias naturales*, will get up and now urinate *per urethram*, and go away rejoicing. (See report of a case in the "Medical Record," vol. xxiii, No. 25, p. 679.)

Such results so easily obtained and an operation so simply performed appear to command no attention with most of our skilled surgeons, and the operation thereby does not receive the credit which should be accorded it.

With this plea for a more general employment of the operation, I again bring it before the profession.

In the "Medical Record," vol. xxv, No. 1, I gave directions for the successful performance of the operation, and will here reproduce them, viz.: "First, select a good galvanic battery which gives a steady, smooth, constant current of the strength of from ten to fifteen volts. The urethral instruments used for the absorption of the stricture are bougies made of metal and insulated with rubber, except the point, which is an olive-shaped silver bulb.

"The recumbent position is the best. To the positive pole a sponge electrode is attached, moistened with water, and placed in the patient's hand or on his thigh. To the negative pole the insulated electrode bougie must be attached, and the instrument should always be inserted into the stricture before connections to the battery be made. It is always advisable to begin the operation with a mild current and increase one cell at a time. The bougie must be gently guided, no force should be used, and no pain should be inflicted. Care must be exercised to keep the bougie in line so that the point will not deviate and make a false passage." To these I will add: An interval of four weeks has proved to give better satisfaction, and will require fewer operations than if performed more frequently.

When acute or subacute inflammation exists, unless the case is an urgent one, the operation had better be delayed until it subsides. In some cases the operation causes a little subacute inflammation, and, if we repeat the electrolysis at too frequent intervals, the urethra may almost close up from the swelling which takes place, and the operator then might become discouraged and abandon the operation. Possibly this has been the reason why some have denounced electrolysis as "of no good" in the treatment of urethral strictures.

As the stricture is partially decomposed, and gradually washed away after each operation, an instrument of about two sizes larger than the caliber of the stricture should be used at each *séance*. For instance, if the stricture admits a No. 11, French scale, bougie, a No. 13 would be the size of instrument for electrolysis. In four weeks the decomposed portion of the stricture will be washed away, and will then, in all probability admit a No. 15, when for our second electrolysis we would use a No. 17, French scale, and so on until we have completed a cure.

The time required to dissolve the stricture depends upon the bulk and extent and kind of stricture we have to deal with. Usually it takes from ten to forty minutes. In two cases, however, where I had to deal with a stricture of from one half to three fourths of an inch in length, it took nearly two hours.

All kinds of urethral strictures can be cured by electrolysis. The following case, with those already reported in

* Longmans, Green & Co., 1882.

different medical journals, will prove the foregoing assertion:

Mr. C. K., aged thirty, had been troubled with an organic stricture for a number of years, and was obliged to use a bougie at short intervals to keep the passage open. On March 5, 1884, from a slight injury received on getting out of a vehicle, inflammatory symptoms set in and in a few hours retention of urine resulted. The usual remedies, opiates, anæsthesia, and the hot bath, were tried; repeated attempts, by several physicians, were made to pass a catheter, but to no purpose. After retention had existed for twenty-four hours I was called to operate by electrolysis. I hesitated, for there was considerable hæmorrhage. As the case was an urgent one and relief had to be given either by puncturing the bladder or by an operation, I concluded to operate by electrolysis. A No. 9 French insulated electrode bougie was introduced to the seat of the stricture, which was at the prostatic end of the membranous portion of the urethra. Connections were made to the galvanic battery with twelve cells in operation. It took one hour for the bougie to pass through the obstruction. Four physicians were present and witnessed the operation. The bougie was withdrawn and the patient urinated. A No. 9 silver catheter was inserted and retained for three days, and the patient made a rapid recovery.

As experience has proved that there is not the slightest danger connected with or resulting from the operation, and that all kinds of strictures of the urethra are amenable to the treatment, certainly this method should be adopted in preference to all others. I again ask that the operation be given a fair, careful, and impartial trial.

A CASE OF EXTERNAL AND INTERNAL URETHROTOMY.*

By L. H. DUNNING, M. D.,
SOUTH BEND, IND.

THE patient, David Holland, aged forty-six years, was seen by me in February, 1884. He had been confined to bed a number of weeks on account of partial retention of urine and an abscess located in the perinæum and adjacent structures along the tract of the urethra. This abscess had been in process of development several weeks, and, at the time of my first visit, had matured, but the patient refused to allow it to be lanced. The following day it ruptured into the urethra, and externally, just above the penis.

When first seen, the patient was voiding small quantities of urine every half hour or every hour. After the rupture of the abscess the ability to void urine was slightly increased. The discharge of pus was profuse.

The patient stated that previous to this attack he had for seven years been unable to voluntarily void urine, and that his inability to so do was ascribed to an enlargement of the prostate gland, following prostatitis. He had evacuated the bladder with the catheter from four to six times a day every day for seven years. The strictures, he stated, had been gradually developing for some three years, and were induced by the careless use of catheters, both by himself and physicians who had treated his case during the time. Just previous to this attack he had used a No. 4 (English) silver catheter, but for the last few weeks had been unable to enter the bladder with any instrument.

I did not at first attempt to pass a sound, but simply advised

rest in bed, administered anodynes and tonics, and directed poultices to be applied to the indurated surfaces in the perinæum and over the pubes.

At the end of three weeks I made a careful examination, and found a much-enlarged prostate gland and three strictures of the urethra, viz.: One, one inch and a half beyond the meatus, one, two inches and a half, and another six inches beyond the meatus. Through the first two I was able to pass a No. 3 (English) sound, but through the third one I could not pass this sound. After considerable manipulation I succeeded in passing a small whalebone bougie, which had the extremity bent to an angle slightly greater than a right angle. Afterward I passed a small catgut bougie, and tried to follow it into the bladder with an Otis tunneled catheter, and then a Gouley tunneled catheter, and failed in both instances. After a few days I tried to pass small, soft bougies into the bladder with success, but the next time failed. So it went on a number of days, when, finding that each effort rendered the strictures more irritable, and the difficulty in passing the urine greater, I desisted, concluding to perform external urethrotomy for the relief of the deeper stricture, and internal urethrotomy upon the first two. Now the patient was voiding urine with great difficulty, using as much force in straining as does a woman in ordinary labor. His suffering was indeed intense. Rest, anodynes, and a milk diet relieved him somewhat, and April 14th we reached a time when we deemed an operation safe and advisable.

The external urethrotomy was done in the usual manner with a guide. The stricture was found to involve the whole of the membranous portion of the urethra, and was freely divided through its whole extent.

After the division of the stricture the catheter (Gouley's) passed readily into the bladder.

Next, I undertook the division of the first two strictures with an Otis's dilating urethrotome, passing the instrument through the orifice. We found ourselves unable to pass the instrument beyond the strictures, notwithstanding the fact that we had repeatedly introduced sounds of larger size than our Otis. An examination through the wound led me to the belief that the instrument could be passed from below upward. This we finally accomplished, but not without the help of a guide.

The beak of the urethrotome appearing at the meatus, it was slightly withdrawn (within the orifice), expanded, the knife drawn out, and the stricture completely divided. The second stricture was similarly treated, with like results.

A No. 13 (English) sound was easily passed into the bladder, and thus were we assured of the success of our efforts.

There was slight hæmorrhage, and the major part of that occurred during the early part of the perineal section. All bleeding stopped, the wound was dressed, and the patient placed in bed.

He rallied readily, and in two hours expressed a desire to urinate. His efforts failed, but brought on quite a severe hæmorrhage. A soft-rubber No. 10 (English) catheter was passed into the bladder and tied there. In forty hours it was removed, cleansed, and replaced, remaining this time thirty-six hours. Now, seeming to cause considerable irritation and pain, it was removed, and a gum-elastic catheter with a double curve was introduced every two or six hours, as required. The third day a No. 13 (English) sound was easily passed through the urethra to the gland. The wound was carefully dressed twice a day, and continued to appear healthy and to rapidly fill with granulations after the third day.

The case passed on in an uninterrupted course for the first ten days, when the patient complained of pain along the tract of the urethra, particularly over the site of the second stricture.

* Read before the Elkhart Medical Society, June 16, 1884.

Upon examination, we found indurated tissue in the space between the second and third strictures.

The swelling was about one inch laterally and two inches in length. It was very tender to the touch, and great pain was experienced in this region upon introduction of the catheter. The pain was so great that I deemed it advisable to tie a catheter into the bladder. This I did, leaving it twenty-four hours, and replacing it by another, which remained twelve hours.

During the next two days the utmost care was required to carry the catheter along the urethra, particularly beyond the site of the second incised stricture. Upon the morning of the fourth day after the operation there was a sudden discharge of pus through the perineal wound, amounting in quantity to six or eight ounces. Simultaneously with this discharge the patient experienced great relief, and in a short time he passed the catheter with ease, and continued to so pass it until his recovery.

Pus flowed from the wound and was discharged from the meatus for ten days, when it entirely disappeared. The swelling gradually subsided, and had entirely disappeared at the end of four weeks from date of operation, and at the end of that time the wound had so far healed as to require but little further attention.

May 16th, thirty-two days after the operation, a No. 13 (English) sound was passed with ease, and has been passed every sixth day since.

Since June 1st the patient has been able to void urine easily in a full, strong stream. He has abandoned the use of the catheter, except, as directed by me, once every day.

On account of the enlarged prostate gland, he is compelled to use a double-curved silver or a Mercier elbow-catheter.

He is now at work, looking well and hearty.

A detailed history of this case is given because of a few points of interest it contains. 1. The manner in which Otis's urethrotome was used in incising the first two strictures, viz.: It was passed from the perineal wound upward. 2. Complete recovery of the patient, notwithstanding the frequent use of the catheter and the formation of an abscess. 3. The complete restoration of the patient's power to micturate after a loss of that power for more than seven years.

PISTOL-SHOT WOUND OF THE HAND; PARTIAL RESECTION OF THE THIRD METACARPO-PHALANGEAL ARTICULATION.

By R. H. WOODWARD, M. D., BRANDON, Vt.,
LATE HOUSE SURGEON TO BELLEVUE HOSPITAL.

JAMES J. WALCH, thirty-four years of age, and a molder by occupation, presented himself for treatment February 22, 1884. He said that four days earlier he had been shot accidentally by a friend who was standing in front of him. The pistol was pointed in such a direction that the bullet must have lodged deeply in the hand. Examination of the injured member disclosed a shot wound on the dorsum of the middle finger, about three fourths of an inch from the metacarpophalangeal joint. There was no other wound about the hand, and manipulation did not furnish any clue to the location of the missile. The dorsum of the hand was quite swollen and red. A probe, passed into the wound, was arrested at about half an inch by a rough substance which was supposed to be shattered bone.

The patient stated that he had been under treatment since the shooting, and that the wound had been probed a number of times. When I first saw him the dressing upon his hand was

so simple that it hardly amounted to a respectable bandage. It seemed to me that the time had arrived for active interference. The third metacarpophalangeal joint had been opened, it was thought, the phalanx was more or less destroyed, and the condition of the hand furnished sufficient reason for suspecting the speedy development of erysipelas. I decided, therefore, to attempt to extract the bullet, and to restore the injured parts to as nearly a natural state as possible. Dr. Henry V. Wildman kindly assisted me during the operation.

Grease and dirt were thoroughly washed from the hand by means of ether, soap and water, and a scrubbing-brush. Elaborate antiseptic precautions were observed from the very beginning until the wound had been dressed. The operation-wounds and their vicinity were irrigated constantly with a 1-1,000 solution of corrosive sublimate during the operation. Since the patient preferred not to take an anæsthetic, ether was not administered, and he was given only one quarter of a grain of sulphate of morphine and an ounce of whisky, although he was on the operating-table about two hours. He did not complain of anything except the sharp-hook retractors, and to them his objection was very mild indeed.

A longitudinal incision was made through the middle of the shot wound on the dorsum of the phalanx, and the extensor tendon exposed. The bullet had perforated the tendon directly in the median line. The tendon was then liberated in such a manner that I was able to draw it aside; and, when that had been done, I found that the proximal end of the phalanx had been seriously damaged by the ball, the metacarpophalangeal joint being opened, and that the phalanx presented also a line of fracture passing obliquely almost from one end of the bone to the other. These two large fragments were held in good position by the soft parts. I scraped out the detritus and injured bone from the cavity where the bullet had impinged upon it, and made a partial resection of the metacarpophalangeal joint. This resection of the joint consisted in the removal of the posterior two thirds of the articulating surface of the phalanx. The condition presented now was, as regards the phalanx, one third of the articular surface, a large cavity, and the shaft of the bone divided into two fragments.

Search for the bullet was begun again at this stage, and a blue spot in the tissues between the second and third metacarpal bones was found. In order to explore the region, it was necessary to enlarge the original incision. It was continued in a curve to the outer side of the injured joint, and between the second and third metacarpal bones to a point opposite their middle. The web between the second and third fingers was cut, but not on its palmar surface. These two incisions were made continuous with each other. Having made these cuts, it was possible to follow the track of the bullet, denoted by a bluish discoloration of the soft parts. The bullet, a No. 32, was found lodged against the second metacarpal bone, midway between its extremities. During this portion of the operation, which was quite tedious, while carefully palpating the hand for signs of the missile, two points were detected, under which, it seemed, the ball might be concealed. On that account a small wound was made in the palm of the hand, which afterward served for drainage, and another, but large cut, was made into the most swollen part of the dorsum of the hand.

The bullet having been extracted, and the soft tissues and the injured bone having been attended to, the capsule of the injured joint was sutured with fine catgut. The wounds were carefully united with continued catgut sutures and drained with several strands of catgut twisted together. Iodoform was dusted upon the wounds, and they were covered with protective. Bichloride gauze, borated cotton, and a splint completed the dressing.

After the operation the patient returned to his home. He did not suffer any pain after the first night. His temperature was never taken, and he did not receive any medicine. On the fifth day the first dressing was removed under antiseptic precautions. The appearance of the hand was perfectly satisfactory; there was no pus, no swelling, no redness. A dressing of the same nature as the first was applied. On the tenth day the catgut sutures were wiped from the wound with a sponge. The wounds had healed by primary union, excepting at a point between the second and third metacarpal bones; at that point there was a small slough. The patient could move the resected joint himself, and there was not a sign of adhesion of the extensor tendon to its surroundings. Passive movements were made and the wound was redressed. The remains of the catgut drains were taken from the wound and the splint was omitted, otherwise this dressing was the same as the preceding. After this the wound was redressed more frequently. The small ulcer remaining from the sloughing healed slowly. Passive motion was given to the joint, both by myself and by the patient. Five weeks after the operation the condition of the parts was as follows: The wounds had healed throughout. The patient could move the resected joint voluntarily through at least one half its normal arc without pain or discomfort. The finger was very nearly as strong as it had been before the accident; the patient had a powerful grip with his injured hand. I thought that still greater movement of the metacarpophalangeal joint could be induced, and proposed more forcible passive motion. The patient requested me to give him ether for this. He was anesthetized, therefore, and I moved the joint pretty freely. The patient was instructed to return for further observation one week later, but I have not seen him since.

Several weeks after my term at the hospital had ended, I received a letter from this patient, in which he informed me that he had been at work, and that his finger was as strong and useful as it had ever been.

A CASE OF HALLUCINATIONS APPARENTLY DEPENDENT UPON MALARIA.

By EDWARD S. DWIGHT, M.D.

I was consulted some time in last October by a man of forty-one, American, of temperate habits, an employee on the Elevated Railroad, who complained of having, during the two preceding months, experienced hallucinations of a rather indefinite character, and which worried him greatly, as he feared that they might be the precursors of insanity. These hallucinations occurred perhaps once a week, attacked him usually when at his work, and were of but momentary duration, although they seemed to him to last for a minute or more. He had great difficulty in recalling the exact nature of these visions, and expressed regret that he was unable to remember and describe them better. The following only he could distinctly recollect: On one occasion he imagined that he saw men in red uniforms passing through the train collecting tickets, which they deposited in leather bags worn at their side; on another, that he suddenly found himself in a "beautiful place," where he beheld a stranger pursuing his wife; that he followed them to see what the man wanted with her, when all at once everything vanished and he found himself, as usual, in the cars; on a third occasion, while seated at the dinner-table, he suddenly imagined himself to be in a green valley, through which a man mounted on a camel was riding.

As I have already said, these hallucinations were of but momentary duration. On the occasion last mentioned the clock

had commenced to strike before the vision appeared, and had not yet ceased when the illusion vanished. He thought that no one had ever remarked his condition when thus attacked, except on this last occasion, when his wife had noticed him to be very pale, and that his face had an unnatural appearance. As soon as an hallucination had passed off he would detect himself looking around to see what had become of the strange people and things he had just seen, and would sometimes find himself debating as to whether he had actually beheld such and such a thing, or whether it was only a reminiscence of one of these dreams.

The attacks were followed by a chill, passing down from the right shoulder to the stomach, to which succeeded nausea. The patient was subject to vertigo, was dyspeptic, and habitually constipated.

His memory was very good. I could obtain no history of insanity in his family, and, one or two symptoms causing me to suspect a malarial influence, I prescribed a course of laxatives, and gave quinine. After two or three days of this treatment all abnormal symptoms disappeared, nor did he have any recurrence of the hallucinations for several months, when a renewal of the same course of medication again put them to flight.

It seemed to me as if in this case a momentary arterial contraction must have occurred, placing the patient's already anæmic brain in the semi-bloodless condition in which the organ is when we doze, and that for the moment, half awake and half asleep, the patient had dreamed while standing erect.

The last time that I saw him he seemed in excellent health, and told me that he was no longer troubled with vertigo or any other cerebral symptoms.

Correspondence.

LETTER FROM STOCKHOLM.

The Social Side of the Eighth International Medical Congress.—Opening of the Congress.—Reception of M. Pasteur.—Dinner given by Professor Panum.—Turkey's Homage to M. Pasteur.—Organizing the Sections.—Reading of M. Pasteur's Paper on Hydrophobia.—Entertainments.—Visiting Historical Localities.

Stockholm, August 23, 1884.

The Eighth International Medical Congress, after a most successful and brilliant meeting, was brought to a close last Saturday night. To give a full history of its proceedings, and of the many incidents which occurred during its progress, would be impossible. From the beginning to the end, each day was filled to its utmost capacity with the work of the sections, special and general, and with the manifold expressions of hospitality, both public and private, extended by our genial and generous entertainers, the Danes. The writer will confine the matter of this letter to a short account of the congress from its social aspect, giving such information as would not be reported in the regular Transactions.

The Congress really began on Saturday evening, August 9th, when an informal reception was held at the Tivoli, a famous evening resort in Copenhagen, and one of the largest and most beautiful of its kind in Europe.

The grand opening of the Congress, held at one o'clock on the day following (Sunday), was largely attended, nearly all of

the delegates having arrived in the city, and was in every respect a notable occasion, graced as it was on the one hand by the presence of a royal family, distinguished alike for its goodness and for the wide influence which it is now exerting upon the political history of Europe, numbering among its members the present King of Greece, the Empress of Russia, and the Princess of Wales, and, on the other hand, by such an assemblage of brilliant, famous, and useful representatives of a noble science as has rarely been brought together.

Looking around upon this remarkable audience, and noting the striking figures, strong countenances, and glittering decorations of those who composed it, the conviction arose that in few other departments of learning could such a company be gathered.

Speeches of welcome were made by Professor Panum and by the secretary of the Congress, Dr. Lange, and the meeting was also addressed by Pasteur, Sir James Paget, and Professor Virchow. The appearance upon the platform of M. Pasteur was the signal for an outburst of applause so strong, spontaneous, and long continued as to have well repaid any man for years of hard work. It was overwhelming, and indicated at once that, in the popular esteem, its subject was the head and front of the occasion. His speech, as was Sir James Paget's, was a model of gracefulness and brevity.

On Sunday evening Professor Panum gave a dinner at the Hotel d'Angleterre to about three hundred distinguished guests. Here, as on other occasions, Pasteur, Paget, Virchow, and Gull were the honored guests. Eloquent speeches were made by all of these gentlemen, Pasteur responding to the toast, "The King of Denmark"; Paget, "To Denmark"; and Virchow, to "The hospitality of the Danes." A striking incident happened during the dinner, when the Turkish Ambassador, gorgeous in the full regalia of his office, approached Pasteur, and, taking his hand in both of his, pressed it reverently to his lips, thus, as the representative of political power, paying to the representative of scientific eminence the highest tribute at his command.

The sections were regularly organized on Monday morning, and the grand event of the Congress, scientifically speaking, took place on Monday afternoon, when, at the great general meeting, Pasteur delivered his address based upon his recent investigations regarding hydrophobia. In this the progress and results of four years of incessant labor were given, simply, clearly, and forcibly, in the space of one single hour. The paper was read with great distinctness, and every word from the beginning to the end was listened to with most earnest attention, until, when the magnificent results attained were announced, the audience expressed itself in enthusiastic applause. This hour alone was well worth the long journey to Copenhagen, and can not fail to be remembered by all present. Monday evening was devoted mainly to dinner parties given by the officers of the various sections to their respective members. The Laryngological Section was delightfully entertained; its members with their lady friends, and numbering in all about one hundred and twenty, being taken upon a beautiful little steamer up the sound to Skodsborg, about an hour's sail from the city, where, nestled against the side of a lovely green bluff, was a handsome summer hotel, at which dinner was served, with Professor Wilhelm Meyer, President of the Sections on Laryngology and Otology, as host. A fine band of music accompanied the party from Copenhagen; the dinner was enlivened by numerous speeches; dancing was indulged in after dinner in a music hall which overlooked the waters of the sound, glittering like silver in the light of the full moon, and finally, after a most delightful evening, the party was escorted back to the steamer to the music of the military band, and in the light of a fine display of fire-works.

Tuesday was taken up with the regular affairs of the Congress, but on Wednesday all business was adjourned, and the whole party, numbering, ladies included, about sixteen hundred, were magnificently entertained throughout the whole day by an excursion to Elsinore and Frederiksborg. At ten A. M. five large and comfortable steamers, gaily decorated with flags, left the principal quay and steamed in single file up the waters of the sound. The day was perfect, both as to atmosphere and temperature, and the sea calm, and in a little over two hours the party was safely landed at the ancient town of Helsingöre or Elsinore, famous for its splendid old castle, the Kronborg, which, rugged and picturesque in architecture, with a tower of extraordinary outline, and surrounded with fine ramparts and broad moats, commands the narrowest part of the sound, here about two miles wide. Shakespeare refers to Elsinore as the residence of Hamlet, and the "Flag Battery," a broad bastion, commanding a beautiful view of the sound, and the shores of Sweden beyond, and upon which the "Dannebrog" or national flag of Denmark is planted, is said to be "the platform of the Castle of Elsinore" where the ghost of the murdered king appeared.

The Kronborg is also the scene of other interesting legends connected with Denmark. Thus, the tutelary genius of the county, Holger Danske, who is familiar to the readers of Andersen's fables, is said to "repose beneath the castle, ready to arise when Denmark is in danger." With the relation of these and many other superstitions, as well as with statements of greater historical accuracy, our genial hosts added greatly to the attractiveness of the place, as we wandered over its halls and towers, and through its intricate system of under-ground passage-ways. An excellent and generous luncheon was served in the castle, and, when the party had been thoroughly refreshed, and several large groups photographed, and when some of us had visited the cairn of stones said to mark the location of Hamlet's grave, and had inspected the corner of the moat in which Ophelia is supposed to have drowned herself, the party took the railway train for another celebrated Danish palace, Frederiksborg, an imposing building, situated upon three small islands in the midst of a lovely lake—the whole presenting a picture of extraordinary beauty. The palace was designed and erected in 1602 by Christian IV, the most talented and famous of the Danish kings, and has, within late years, been superbly decorated inside in the "late rococo" style.

After again driving through the quaint old town, the depot was reached, and the party soon landed back in Copenhagen, after a day of complete enjoyment to all.

Responsibility for Certificates of Insanity.—A case recently reported in the last volume of the "Maine Law Reports" brings up the question whether a physician is responsible in a civil suit for damages for the incorrectness of the certificate given in an examination of a person alleged to be insane, and upon which a commitment was issued. The Court held in a case of this kind that any defects in the form of the certificate should have been rectified by the committing magistrate, and that, if the law had not been fully complied with, the order should not have been made. For any fault of this kind, which was more legal than medical in its character, the magistrate was liable rather than the physician. What the latter was liable for was an untruthful or malicious statement of facts, or the opinion as to insanity based upon them. If the physician should certify to an examination which had not in fact been made, such a breach of professional honor would, no doubt, make the offender liable in a suit for damages. A plain and honest statement of facts, as discovered by the physician, with a carefully prepared opinion based upon these facts, would never subject the physician to the danger of a verdict for damages in case he should turn out to be mistaken.

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, SEPTEMBER 20, 1884.

THE DROP, THE MINIM, AND THE SPHYGMOGRAPH.

DR. KEENE'S paper, "One Drop," read at a recent meeting of the Buffalo Medical Club, and to be found elsewhere in this issue of the journal, seems to call for some comment as regards those matters mentioned in the caption of this article.

To begin with the sphygmograph. Much may be pardoned in a writer who presents a subject so attractively as Dr. Keene presented the inaccuracies of the method of measuring liquids by drops, and, beguiled by the same persuasive to forbearance, we may forego more than an allusion to the proverbial aversion of hobby-riders to other steeds than their own. We can not refrain, however, from a mild protest against the depreciatory way in which the writer of the paper thought fit to refer to the sphygmograph, and we wonder that at least one member of the club, whose work in sphygmography is well known, should have let the allusion pass without comment. We can only explain that gentleman's silence by supposing that he must have found himself in much the same frame of mind as the rustic, famous in story for his profanity, who—on an occasion when some of his acquaintances, eager to sound the depth of his capabilities in swearing, deliberately watched his cartload of apples roll down a long hill that he was climbing, and called his attention to the fact only when he had reached the summit—dodged the snare that had been laid for him by the simple remark that words were unequal to the situation.

To come to the matter more immediately and directly dealt with by Dr. Keene: no doubt the drop is aggravatingly vague, but the adoption of a particular method of delivering drops would, it seems to us, go far toward reducing their indefiniteness within practically insignificant limits—limits quite as narrow as those that bound the variations of minim-glasses. It would be interesting to compare the graduation of these glasses as furnished by different makers, and we suspect that such a comparison would not show wholly to the disadvantage of the drop. A further drawback to our entire trust in the minim-glass is to be found in the fact that the surface of a column of liquid contained in such a glass does not form a dead level, so that the indication is likely to be read off differently by different observers. Some weight may be attached, too, to the circumstance that, when a certain number of minims have been measured off in the glass, they can not be wholly transferred from it without dilution, and the quantity that remains adherent to the glass varies according to a diversity of conditions, such as the temperature, the viscosity of the liquid, and the shape of the glass.

Liquids can of course be measured accurately, even to small

fractions of a minim, but we doubt if, on the whole, any method will be found more satisfactory for ordinary use than the dropping process. Accuracy might be gained by the simple expedient of weighing instead of measuring, but to unlearn our doses by measure and to learn a fresh set of doses by weight would involve all the vexation that has thus far attended the attempt to bring the metric system into use among us—an attempt which seems to us certain to fail, and, moreover, to be deserving of failure.

PASTEUR AND KOCH.

DECORATED in France, received back in Berlin with enthusiastic demonstrations of admiration, his utterances concerning the comma bacillus published *verbatim* in the Berlin medical journals, given in abstract in those of other countries, and even caught up by the secular press—Koch may fairly be said to be basking in the sunshine of popular esteem. It must be very encouraging, and not a little gratifying, to the votaries of science to see one of their number honored as the world of but a few years ago was wont to honor only military heroes; the spectacle makes a living truth of the dictum that "peace hath her victories no less renowned than war." The world moves, and he who forces the occult energies of nature into the service of mankind, or curbs their power for harm, comes forward with no faltering step to dispute the place of honor with the greatest of slaughterers.

Moreover, it is not to any glamour emitted by Koch personally that the popular homage is due, for Pasteur is likewise borne on men's shoulders. It is well known that he was the lion at the reception given by the King of Denmark to the International Medical Congress, and we have private information to the effect that the paper which he read before the Congress was of such a wonderful nature that men whispered freely to each other that Koch had done well to stay away. Both these great men, then, have no lack of admirers, but each—in truth it must be said—has his detractors. An editorial writer in the "Union médicale" asks, concerning a blockhead who has proposed to treat cholera by drawing the intestinal liquids to the skin by means of pilocarpine, "Is he less of a physician than he who has said: 'Deprived of water, my microbe dies on a slip of glass; therefore the drains of cities should be dried up'?" On the other hand, we have heard it said against Pasteur that he declined to make his processes known, and that, consequently, nobody was able to test his work. Perhaps Paul Pry has visited him too often in the past, with the result of putting him constantly on guard against meddlers.

Pasteur and Koch have not openly put themselves in an attitude of antagonism; let us not urge them on to any such unseemly course. Whatever may prove to be the practical utility of the preventive inoculation of rabies, and whatever rôle may finally be assigned to the comma bacillus in the etiology of cholera, both these men have taken great strides in leading investigation of the lower organisms in the paths of progress; each is playing his part well, and each may be honored without detracting from the other.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 16, 1884:

DISEASES.	Week ending Sept. 9.		Week ending Sept. 16.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	1	0	0	0
Typhoid Fever	56	16	32	17
Scarlet Fever	31	9	27	8
Cerebro-spinal meningitis	4	4	4	4
Measles	39	12	22	11
Diphtheria	17	5	29	17

Cholera Resolutions.—At a meeting of the Chicago Medical Society, held Monday, September 15th, Dr. L. H. Montgomery presented the following resolutions:

Whereas, From present reports and indications in foreign countries, cholera and yellow fever (both pestilential diseases) prevail, and as the latter especially is always assuming a threatening attitude toward us and is not conducive to our national prosperity nor to public health, and should, if possible, be averted with earnest and efficient sanitary measures, and

Whereas, Cholera may make its appearance on this continent ere another twelve months should elapse, and should likewise, if possible, be averted or restricted to the narrowest limits, therefore,

Resolved, That it is the sense of the Chicago Medical Society to have that department of the Government relating to public health recognize the services of able sanitarians who constitute the National Board of Health, for the purpose of co-operating with municipal, State, and other organizations of a similar kind, and that a committee of five or seven members of this society be appointed by the Chair to draft suitable resolutions in behalf of said National Board.

Resolved, Furthermore, that this committee present said resolutions to the Congress of the United States, memorializing that body to make a sufficient appropriation for the purpose of said board for scientific investigation in the prevention and restriction of epidemic, preventable, and pestilential diseases.

We believe this action should be promptly taken at the coming session of our National Legislature, and that a thorough sanitary organization of the nation should be recognized, and with it absolute enforcement of the best means for the protection of her citizens and the improvement of our inter-state sanitary condition.

The New York Polyclinic.—The next session of the Polyclinic will begin on Monday, the 22d inst., with enlarged accommodations and increased facilities for instruction. The new building, recently purchased, has been fitted up with special reference to the comfort and clinical instruction of the classes. Three new rooms, capable of seating in all about three hundred, have been supplied with every convenience; a laboratory for Pathological Histology and Clinical Chemistry, with a capacity for about thirty, has been fitted up; for the Eye, Ear, Throat, and Nose clinics there are thirty-one stalls, supplied with Mackenzie condensers, and the library and waiting-room has been enlarged.

The following clinics will be given weekly during the coming season: Surgical, eighteen; Gynecological, sixteen; Diseases of Children, six; Diseases of the Skin, six; Diseases of the Nervous System, six; Diseases of the Eye, ten; Diseases of the Throat, Nose, and Ear, six; Obstetrical, three; Clinical Chemistry, three; Diseases of the Chest, Diagnosis, and Medicine, eight—in all, eighty-two clinics each week. There are no changes in the corps of instructors.

The managers and faculty are to be congratulated, not only on the purchase of a property so well adapted to their purposes, but also on the marked success which has attended their efforts.

The Cartwright Prize of the Alumni Association of the College of Physicians and Surgeons of New York is open to the competition of alumni of any medical college.

It consists of a prize of *five hundred dollars* to be awarded to the best medical essay submitted upon any subject the author may select. The award will be paid as soon as the successful article shall have appeared in print.

If no one of the competing essays be deemed sufficiently meritorious, the prize will not be awarded.

An essay, in order to be held worthy the prize, must contain the results of original investigation made by the writer.

An award of this prize will be made at Commencement, 1885. Essays must be sent to a member of the Prize Committee before April 1, 1885.

Competing essays must each be marked with a device or motto, and accompanied by a sealed envelope, similarly marked, containing the name and address of the author.

R. W. AMIDON, M. D., 18 West Twenty-first St., *Chairman*,

ROBERT ABBE, M. D., 32 East Twenty-fifth St.,

WALTER MENDELSON, M. D., 209 West Forty-sixth St.,

Committee on Prize Essays.

The Late Dr. Robert J. Heinmüller.—At a special meeting of the members of the Fourth Division of the Health Department of the City of New York, held September 2, 1884, the following resolutions were adopted:

Whereas, We have learned with deep sorrow and regret of the death of our late colleague, Dr. Robert J. Heinmüller, therefore be it

Resolved, That in the death of Dr. Heinmüller this department has lost one of its most faithful and efficient officers, and we, his associates, a friend whose many noble qualities of mind and heart had endeared him to each and all of us. And the profession has lost one of its most promising young members.

Resolved, That we tender to the family of the deceased our deepest sympathy in their great bereavement.

Resolved, That a copy of the proceedings of this meeting be sent to the family, and to the medical journals for publication.

J. C. CONOVER, M. D., }

A New Italian Medical Journal, devoted especially to diseases of the genito-urinary organs, is, according to "Ann. des mal des org. gén.-urin," to be established in Pisa.

The Death of Professor Cohnheim, whose contributions to our knowledge of the pathology of inflammation are well known, is reported to have taken place at Leipzig on the 16th of August.

The Mississippi Valley Medical Association (formerly the Tri-State Medical Society) will hold its next meeting in Representative Hall, State House, Springfield, Ill., on Tuesday, Wednesday, Thursday, and Friday, the 23d, 24th, 25th, and 26th inst.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 7, 1884, to September 13, 1884:*

GREENLEAF, CHARLES R., Major and Surgeon. To conduct a detachment of recruits to the Department of the Columbia,

and, upon completion of this duty, rejoin his station, Columbus Barracks, Ohio. S. O. 210, A. G. O., September 6, 1884.

GORGAS, W. C., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Randall, Dakota Territory. S. O. 98, Department of Dakota, September 5, 1884.

EGAN, P. R., First Lieutenant and Assistant Surgeon. When relieved by Assistant Surgeon Fisher, to report at Fort Lowell, Arizona Territory, for duty as post surgeon. S. O. 82, Department of Arizona, September 2, 1884.

MACAULEY, C. N. B., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Sisseton, Dakota Territory. S. O. 99, Department of Dakota, September 6, 1884.

FISHER, W. W. R., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Apache, Arizona Territory, relieving Assistant Surgeon Egan. S. O. 82, C. S., Department of Arizona.

EWING, CHARLES B., First Lieutenant and Assistant Surgeon. Assigned to duty as post surgeon at Fort Stanton, New Mexico. S. O. 177, Department of the Missouri, September 6, 1884.

MCCLAW, W. D., First Lieutenant and Assistant Surgeon (recently appointed). To report in person to the commanding general, Department of the Missouri, for assignment to duty. S. O. 209, A. G. O., September 5, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending September 13, 1884:*

HEYL, T. C., Surgeon. Relieved from the Adams, September 8, 1884, and ordered to the receiving ship Independence, Mare Island, Cal.

Society Meetings for the Coming Week:

MONDAY, September 22d: Medical Society of the County of New York.

TUESDAY, September 23d: New York Dermatological Society; Medical Society of the County of Lewis, N. Y.; Jersey City Pathological Society (private); Mississippi Valley Medical Association (Springfield, Ill.—first day).

WEDNESDAY, September 24th: New York Pathological Society; The American Microscopical Society of the City of New York; Auburn, N. Y., City Medical Association; Mississippi Valley Medical Association (second day).

THURSDAY, September 25th: New York Academy of Medicine (Section in Obstetrics and Diseases of Women); Materia Medica Society, New York; Harlem Medical Association of the City of New York; New London County Medical Society (New London, Conn.); Mississippi Valley Medical Association (third day).

FRIDAY, September 26th: Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Mississippi Valley Medical Association (fourth day).

Letters to the Editor.

WHAT WE REALLY KNOW ABOUT ASIATIC CHOLERA.

NEW YORK, September 1, 1884.

To the Editor of the New York Medical Journal:

SIR: I have been exceedingly interested in Dr. Bartlett's suggestive article in your issue of August 30th. But a sufficient

number of well-established facts are known to account for all the peculiarities and vagaries of cholera.

1. Cholera has existed in Hindostan for centuries. It was found there by Vasco da Gama in 1496, and there is a perfectly authentic history of it from that time down to the present.

2. It is never absent from India, from whence it has been conveyed innumerable times to other countries. It has never become domiciled in any other land, not even in China, parts of which lie in the same latitude; nor in Arabia, to which country pilgrims go every year from India; nor in Egypt, nor Persia, with which communication is so frequent; much less in any other part of the world. Canton in China, Muscat and Mecca in Arabia, lie nearly in the same degree of latitude as Calcutta, in which cholera is always existent; yet these places only have cholera occasionally, and then only after arrivals of it from Hindostan.

3. The arrival of cholera in other countries is often involved in some easily removable obscurity, which is deepened only by the ignorance and want of veracity of quarantine and other officials.

4. Cholera is almost always preceded by a premonitory diarrhœa, which lasts from one or two to three or four or more days before urgent and characteristic symptoms show themselves. Of 6,213 cases, no less than 5,786 had preceding diarrhœa. The sufferers from this sow the germs of the disease in numerous, often distant and obscure places, to which no choleraic person is supposed to have come.

5. The discharges swarm with infective bacteria of various kinds, some of which, especially Koch's comma bacilli, seem to be specific.

6. The disease has been reproduced in men and some few animals by their swallowing the discharges.

7. The discharges, according to the experiments of Thiersch, Burdon-Sanderson, and Macnamara, are not virulent and poisonous for the first twenty-four hours; on the second day eleven per cent. of those who swallow them will suffer; on the third day, thirty-six per cent.; on the fourth day, ninety per cent.; on the fifth day, seventy-one per cent.; on the sixth day, forty per cent.; and after that the discharges have no effect—the bacteria die, and the poison becomes inert.

Professor Robin reproduced cholera in dogs, and the celebrated dog Juno died of cholera in Egypt last year. Professor Botkin, of the University of Dorpat, reproduced cholera in dogs by the subcutaneous injection of the urine of cholera patients. Even if the comma bacilli are not found in the urine, other bacteria are; and even Koch supposes that they secrete a virulent poison similar to that of some insects, which may be absorbed into the blood and escape from the kidneys.

8. Some of the manners and customs of the Hindoos are very peculiar. They always defecate upon the open ground, and will not use privies or latrines. This is a matter of religious obligation with them. It is also obligatory upon them to go to stool every morning; to use the left hand only in wiping themselves; to wash their fundaments after stool; to wash their whole persons and clothing every day; and, finally, also to rinse their mouths with water, and this they often do after washing in foul tanks, or still fouler pools of water. On steamships, where tubs of water were provided for washing their fundaments after defecation, Surgeon-General De Renzy saw many Hindoos rinse their mouths with the same water.

9. The population of Hindostan is nearly three hundred millions, and at least one hundred million pounds of fecal matter is deposited on the open ground every day, and has been for centuries.

10. Much of this foul matter is washed by rains into their

tanks and pools of water, which they use indiscriminately for washing, cooking, and drinking purposes.

11. The poison of cholera has repeatedly been carried in soiled clothing packed in trunks and boxes, and conveyed to great distances.

12. Articles of food, even bread and cake, as well as apples, plums, and other fruit, handled by persons in the incipient stages of cholera, have been known to convey the disease.

13. The number of epidemics produced by cholera discharges getting into drinking water are almost innumerable, and those from contaminated milk are not few.

14. The first case of cholera is generally counted from the first fatal one, whereas this is almost always preceded by non-fatal ones, which have escaped notice. And each subsequent fatal case is interwoven by one, or several, or even many, non-fatal cases. If the string of a row of beads is broken, and the beads scattered everywhere, it would be just as improper to say that they had never been upon a string as to say that, because all the fatal cases of cholera can not be traced to equally fatal ones, no connection ever existed between them.

These points are necessarily stated categorically, but every one can be proved, if proof is called for. The numerous and very large pilgrimages of the Hindoos must not be forgotten.

JOHN C. PETERS, M. D.

83 MADISON AVENUE.

Proceedings of Societies.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE thirty-third annual meeting was held in Philadelphia, September 4 to 10, 1884, the President, Professor J. P. Lesley, of Philadelphia, in the chair. We give short abstracts of only a few of the more important papers having a bearing upon medicine.

Thursday—First Day.

The meeting was called to order by the retiring president, Professor C. A. YOUNG, of Princeton, N. J., who, after an invocation by Rev. HENRY C. MCCOOK, D. D., of Philadelphia, resigned the chair to the President-elect. Addresses of welcome were made by His Excellency ROBERT E. PATTISON, Governor of Pennsylvania, and by His Honor WILLIAM B. SMITH, Mayor of Philadelphia. After the transaction of general business, the General Session adjourned and the various sections were organized.

Friday—Second Day.

Section in Physics.

Sensitiveness of the Eye to Colors of a Low Degree of Saturation, by Professor E. L. NICHOLS, of Kansas:

For the purpose of determining the minimum degree of saturation at which various pigments become perceptible to the average observer, red lead, chromate of lead, chromic oxide, and ultramarine were each mixed with white, and a series of compounds formed in white; the proportions of the pigment to white were 1:1, 1:2, 1:4, 1:8, 1:16, etc. This process was carried on until the mixtures obtained showed no trace of the hue of the pigment. The four series of mixtures thus formed were bottled and labeled. They were mingled indiscriminately, and the ability of observers unacquainted with the code of labels to arrange the colors according to hue and shade was determined. Fifty-four persons of both sexes were tested in this

manner. From the success of these observers in arranging the colors, two sets of statistics were obtained. The first and most important dealt with the sensitiveness of the eye to the presence of small amounts of coloring matter in mixtures consisting mostly of white.

The amount necessary to impart a recognizable hue to a white powder was found to be almost incredibly small. It differed with the nature of the coloring matter and with the individual observer. Eight of the fifty-four observers (five males and three females) could detect three parts of yellow in one hundred million parts of white. Two observers (both females) could not perceive the colors in mixtures containing less than one hundred and ninety-eight in one hundred millions. The following table gives the average sensitiveness of the two sexes and of all the observers:

Number of Parts of Coloring Matter that must be mixed with One Hundred Million Parts of White to affect the Tint of the Compound.

	Red lead.	Lead chromate.	Chromic oxide.	Ultramarine.
Average for 31 males.....	15.9	17.3	817.7	148.5
Average for 23 females.....	39.8	33.2	913.6	108.1
Average for both sexes.....	25.2	23.9	864.3	126.5

As will be seen, the male observers showed measurably greater sensitiveness to all colors excepting blue, and their superiority increased with the wave-length, being greatest for the red. Both sexes showed a marked deficiency in their power to detect the presence of green, a result possibly of the continued exposure of the eye to that color (in foliage, etc.), and consequent enfeeblement of the nerves corresponding to green. For purposes of illustration merely, a place in the spectrum was assigned to each pigment by the author, and curves were drawn to show graphically the sensitiveness of the eye as a function of the wave-length and to exhibit the peculiarities of this function in each sex and in the case of certain individuals.

In the detection of shades of saturation, women showed a decided superiority in all parts of the spectrum, and both sexes were most successful with the color (green) for which the eye had been found most deficient in sensitiveness.

This would seem to indicate that the power to perceive colors of very low saturation depended upon the delicacy of the eye, while the ability to detect differences of shade was the result of practice.

Chemical Section.

The Opening Address, by Professor JOHN W. LANGLEY, of Ann Arbor, Mich., vice-president of the section, was a historical review of the subject of chemical affinity and the quantitative measurement of affinity, and a statement of existing problems. These he concluded must be solved by accurately measuring the time element in chemical action in determining the rate of speed of chemical combination.

Fish as an Article of Food.—Professor W. O. ATWATER, in his paper on the chemistry of fish, contended that it had been shown that fish was as readily digested as flesh meat. Oysters, however, he regarded as far less nutritious than fish.

Microscopical Section.

Some New Microscopical Devices.—Dr. R. H. WARD, of Troy, N. Y., described the following new forms of microscopical apparatus:

1. A new illuminating arrangement called the iris illuminator, which consisted of an iris diaphragm with decentering adjustment, combined with an Albe illuminator or other condensing system of lenses in such manner that the illuminating

pencil of sight could be accurately graduated, not only in an axial, but also in an oblique direction.

2. A new lens-holder with long arm and with fine adjustment, with which magnifying lenses of either low or high power could be firmly supported and accurately focused at sufficient distance from the supporting pillar to be used in examining mounted herbarium specimens, or other objects widely distributed on the laboratory table.

Recent Studies on the Theory of the Microscope, and their Practical Results as regards the Use of the Microscope in Scientific Investigations.—Mr. R. HITCHCOCK, of Washington, D. C., read a paper with this title. [The full text of Mr. Hitchcock's paper will appear in a future number of this journal.]

Description of the Schroeder Camera Lucida.—Mr. HITCHCOCK described the construction of this instrument, and illustrated the manner of using it. It was, in his opinion, superior to any other form of camera lucida in that the point of the pencil could be distinctly seen, even when the illumination of object and paper was not carefully adjusted. The pupil of the eye was not divided over a reflecting prism, as in the instrument with two prisms by Zeiss, but considerable latitude in the position of the eye was allowed. The field of view was large, and the image of the object was seen projected well out from the foot of the microscope. The pencil was seen directly, the image of the object by reflection. The principle was an adaptation of the binocular prism devised by F. H. Wenham, for use with high-power objectives.

Biological Section.

The Influence of Oxygenated and Un-oxygenated Blood, as well as of Blood in Various Degrees of Dilution, on the Heart of the Frog and Slider Terrapin.—A paper with this title was read by Dr. H. G. BEYER, of the Navy, tending to prove beyond all doubt the highly stimulating influence of well-oxygenated blood upon the heart's action and on its contained nervous apparatus, as well as the unmodified depressing influence on the same of deoxygenated or asphyxiated blood.

To this report a number of experiments were appended, proving these points conclusively. This paper also contained a description of an improved method for working with the isolated heart of the terrapin, especially valuable for pharmacological experiments.

The Existence and Dorsal Circumscription of the Porta (Foramen of Munro) in the Adult Human Brain.—Professor BRIE G. WILDER, of Ithaca, N. Y., read a paper in which he stated that he had been able to determine the existence and dorsal boundary of the porta in all the human brains examined for that purpose, including several adult as well as fetal and young brains. Some of these were prepared by the process of continuous celiacal injection with alcohol. The photographs shown were believed to be the first ever made of "the foramen of Munro." In the enlarged one the orifice was seen to be bounded caudad by the thalamus, cephalad by the forniculum, ventrad by the continuity of the two, and dorsad by the endyma reflected from the parts named upon the intruded portplexus. This demonstration of the dorsal limit of the porta was equally a demonstration of the ventral limit of the rima (great transverse fissure), with which the porta was usually but erroneously made continuous in both figures and descriptions.

Monday—Third Day.

Biological Section.

Experimental Researches on the so-called Thought-Transference was the title of a paper, by W. F. BARNETT, which

showed that perhaps nine tenths of the cases of alleged mind-reading were simply muscular transferences, but that there was an undoubted residuum that could only be accounted for by the action of mind upon mind.

Objections to some Commonly Accepted Views of Heredity.—Mr. ALPHEUS HYATT, of Boston, read a paper in which he said that heredity had no need of the gemmule hypothesis, or pangenesis, but could be equally well understood upon the supposition that the nuclei of cells were the immediate agents of the transmission of characteristics. He then presented the case of a man in Maine who resembled the mother on one side and the father on the other as an illustration of his theory, and contested Professor Brooks's position with regard to heredity.

Researches on Growth and Death was the title of a paper by Mr. C. S. MINOT, of Boston, whose investigations had for their purpose to contribute to the solution of the problem of the effects of age upon organisms, and the manner in which age caused death. He dealt first with the problem of growth, the most obvious of the effects of age, and presented the results of his experiments, covering over three years and including nearly ten thousand measurements of the weights of growing animals, chiefly Guinea-pigs. These statistics would give us a new insight into the matter, because they covered the whole period from birth to maturity, thus enabling us to calculate the rate of growth for the entire post-fœtal interval. Hitherto the actual increments of growth had been compared directly with one another, but, if we adopted a new and correct method of comparison, we should reach a conclusion, he believed, of great importance—viz., that the rate of growth steadily diminished from birth onward, so that the loss of power began at once and continued until it culminated in death. The new method consisted in calculating the average daily increment during a given time in percentages of the weight at the beginning of that time. The series of percentages thus obtained might legitimately be compared with one another and yield the result he had given. Another manner of demonstrating the same relation of potential power at different ages was to calculate by interpolation the length of time necessary to add ten per cent. to the weight. It was found that the older the animal was the longer it required to increase ten per cent. His measurements by various methods of grouping threw much light on the loss of weight in some animals immediately after birth, on the relative growth of males and females, on the effects of reproduction on growth (which were the reverse of what Herbert Spencer had asserted), on the dependence of the size, number, sex, and weight of the young upon the age of the mother, the season of the year, etc., and on the determining causes of sex. These subjects would all be treated of statistically. He wished to discuss particularly the bearing of the results obtained on the general theory of senescence, and to criticize from the new standpoint the views on death recently emitted by Weissmann, Goette, Buetschli, and others. In this connection it would be necessary to attack the current conceptions of animal individuality. In the course of this discussion he would show that the results obtained in regard to the growth and other phases of development of man agreed closely with the deductions from his own experiments. In conclusion, he wished to refer briefly to the bearing of our present knowledge of senescence upon the theory of life and the relation of life to a material substratum.

Do the Cerebellum and the Oblongata represent Two Encephalic Segments, or only One?—In a paper with this title, Professor WILDER remarked that, since the publication of von Baer's "Entwicklungsgeschichte," in 1837, the segmental constitution of the brain had been more or less distinctly admitted by most writers who had treated of the organ in the light

of embryology and comparative anatomy. Further investigations in embryology and comparative anatomy were needed to place any segmental formula of the brain upon a satisfactory basis, and the objections made by Spitzka should not prevent us from employing von Baer's interpretation as a working hypothesis.

Microscopical Section.

Electric Illumination for the Microscope, with Practical Illustration, was the title of a paper read by Mr. W. H. WALMSLEY. He used a Swan lamp both for opaque and for transparent objects, and an objective of one fourth to one fifth inch.

Tuesday—Fourth Day.

Biological Section.

Ethidene Dichloride as an Anæsthetic.—Professor J. G. McKENDRICK, of Glasgow, Scotland, read a short account of the physiological action of ethidene dichloride ($C_2H_2Cl_2$) on the lower animals and on man, showing wherein it differed from the action of chloroform and ether, especially as regarded its action on the heart, on blood-pressure, and on respiration.

Preliminary Notes on the Delicacy of the Special Senses.—Mr. E. H. S. BAILEY, and Mr. E. L. NICHOLS, of Lawrence, Kansas, furnished a paper embodying the results of researches to test the delicacy of the special senses, particularly sight, smell, and taste, in persons of different nationalities and both sexes. One of the authors had presented the result of experiments on the "sensitiveness of the eye to colors of a low degree of saturation." To test the delicacy of the nerves of taste, solutions of sulphate of quinine, cane-sugar, common salt, sulphuric acid, and baking soda were employed. A series of dilute solutions was prepared in which each sample was of half the strength of the previous one. The result of the tests thus far made was as follows:

	Sulphate of quinine.	Acid.	Salt.	Sugar.	Alkali.
Average of 29 males, one part in	152,000	1,760	640	208	48
Average of 20 females, one part in	144,000	2,560	760	288	60
Average of both sexes, one part in	148,000	2,060	700	248	54

In all cases except the detection of the bitter substance the females were above the average. The tests for the delicacy of the sense of smell were being made in a similar way, using as test solutions oil of cloves, nitrite of amyl, extract of garlic, solution of bromine, and cyanide of potassium. These solutions were diluted in a similar way to those above described, and, although tests had been made with only thirty-four persons, they pointed strongly to the inference that the sense of smell was more acute in males than in females. Many could not distinguish between a strong solution of cyanide of potassium and pure rain-water.

Wednesday—Fifth Day.

Biological Section.

Experimental Research relating to the Etiology of Tuberculosis.—Dr. G. M. STERNBERG, of the army, read a paper in which he stated that he had repeated Koch's inoculation experiments, and was able to confirm him as to the infectious nature of tuberculosis, and also as to the presence of the bacillus discovered by him in the tubercle nodules in the lungs and in tuberculous glands of inoculated rabbits and Guinea-pigs (inoculated with the sputum of phthisical patients). The experiments

of Formad, of Philadelphia, in which he professed to have produced tuberculosis in rabbits by the introduction into the cavity of the abdomen of finely powdered inorganic material, had also been repeated with an entirely negative result so far as the production of tuberculosis was concerned. The conclusion was therefore reached that the bacillus of Koch was an essential factor in the etiology of tuberculosis.

An Induction of the Law of Repetition, or the Growing Principle of Nature, from Observations of the Growth of Character in Three Infants, by VIRGINIA K. BOWERS, was a paper intended to show that character was developed by repetition or habit from certain universally implanted tendencies and faculties of the human race.

Dr. H. P. BOWDITCH, of Boston, gave a brief description of some **Experiments on the Action of the Vaso-motor Nerves of the Leg**. The experiments were made on cats curarized and kept alive by artificial respiration. The sciatic nerve was divided, and stimulated peripherally with induction-shocks of varying intensity and rhythm. The leg of the animal was inclosed in a glass vessel provided with a rubber collar fitting closely round the shaved and greased skin of the thigh. This vessel could be filled with water of any desired temperature, and the air-space in the upper part of the vessel being in communication with a delicate Marey's drum, the changing volume of the leg was recorded upon the surface of a cylinder covered with smoked paper and revolving once an hour. The results thus far obtained showed that slow, rhythmical stimulation (once in a second) caused dilatation, as a rule, while rapid stimulation (twenty times in a second) generally produced contraction of the vessels of the leg. The contraction occurred very promptly upon the beginning of the stimulation, and ceased when the stimulation ended, while the dilatation was produced much more slowly, reaching its maximum usually after the end of the stimulation. The effects of varying temperature and of variations in the length of time elapsing between the section of the nerve and the stimulation would be subjects of future investigations.

CHICAGO MEDICAL SOCIETY.

Meeting of September 1, 1884.

The President, Dr. A. K. STEELE, in the chair.

Remarks on Aneurysms was the title of a paper read by Dr. J. A. ROBISON. After some remarks on the etiology, pathology, and diagnosis of aneurysms, the reader said that the general principles governing the treatment had been to prohibit the patient from taking much exercise, to secure as nearly as possible absolute rest, and to restrict the diet. When the heart's action was tumultuous, cardiac sedatives were to be given, and such symptoms as dyspnoea, pain, etc., had to be met with appropriate palliatives. The first attempt at specific treatment for internal aneurysms was employed many years since by Albertini and Valsalva, and had been known as Valsalva's method. It consisted in weakening the patient by repeated blood-lettings, and by gradually diminishing his meat and drink, till only half a pound of pudding was taken morning and evening, with a measured quantity of water, so that at last the patient was so exhausted that he could not lift his hand from the bed, in which he was ordered to lie from the commencement of the treatment. When this stage was reached, the amount of nutriment was increased until the patient's strength was restored. This plan of treatment had not yielded the beneficial results which were anticipated. In our day it would be regarded as barbarous if carried to the extreme.

A modification of this method, consisting of enforcing absolute rest, and lessening the food and drink so as to diminish the

quantity, but not the physiological quality, of the blood, had benefited a number of patients if it had not entirely cured them. While some physicians had refused to employ the depleting treatment, they had resorted to measures fully as severe. Dr. Murchison and Dr. Moore, of England, had recommended, and in one case tried, the introduction of fine wires into the aneurysmal sac, on the theory that the large amount of surface exposed to the circulating fluid would produce coagulation of the fibrin. In the case referred to, they introduced twenty-six yards of fine iron wire into the aneurysmal sac, and, it was needless to say, the treatment was unsuccessful, although they contended that the result obtained had demonstrated that the principle was sound, and that further experiments were justifiable.

A much less dangerous and probably more efficient mode of treatment was by electrolysis. Pravaz was the first to use electrolysis for reducing external aneurysms, and Cincelli and others had applied it to internal aneurysms, but of eight patients with thoracic aneurysm only one was benefited. Only one with abdominal aneurysm was cured, and this patient died from rupture of the sac on account of premature exertion. The results obtained from the use of the galvano-puncture had not justified us in expecting much from that method. Professor Langenbeck had published accounts of two cases which he stated he had cured by hypodermic injections of from half a grain to three grains of Bonjean's watery extract of ergot every three days. Balfour had tried this method frequently, but without any success. Pressure as a mode of treatment was wholly inapplicable to thoracic aneurysms, and nearly so to abdominal. Dr. Murray had recorded a case of the latter in which pressure on the aorta for five hours, the patient being under chloroform, had been successful.

In the treatment of internal aneurysms, it was conceded by Flint and Bramwell, and insisted on by Balfour, that iodide of potassium was the only drug which offered any hope of cure, and in every case it would relieve the distressing symptoms. The latter author said: "Of all the various modes of treating internal aneurysm, there is not one hitherto mentioned which is not attended with considerable risk or danger except Mr. Tuffnell's plan of perfect rest, while the advantages to be derived from some of them are, to say the least, very problematical."

Dr. Robison maintained that the treatment by iodide of potassium was perfectly safe and certain to afford relief, although relief was not always to be got instantaneously. It relieved the pain and other symptoms more rapidly and more effectually than any other treatment, apart even from the powerful agency of the recumbent posture. The relief to the pain and other symptoms was so great and so speedily obtained, usually from the action of the drug alone, that it was often difficult to get the patient to submit to any restrictions.

He had employed this method of treatment during the last eight years, in a very considerable number of cases, with unvarying success so far as the relief to symptoms was concerned, and with such favorable results as to retarding the further progress of the case—even in some cases promoting an apparent cure—as certainly to stamp this treatment as one of the most efficient hitherto proposed. Balfour related the history of twelve cases treated by this method with the following results: The symptoms, such as pain, dyspnea, etc., were relieved in every case; the physical signs of aneurysm were diminished in seven cases; pulsation of the tumor ceased in two cases, diminished in four, and was not apparent from the commencement in six. The aneurysmal tumor disappeared in three cases and diminished in five, the *bruit* disappeared in two cases and diminished in two, but in two it had never existed. Five of the patients were so relieved that they could work; four were discharged at their

request, feeling well; one absconded, and the result of the treatment was not known. Five were termed cured, and seven were relieved. One of the twelve cases referred to was an aneurysm of the innominate artery, which was cured, and Balfour professed to have cured several cases of aneurysm of this artery.

One of the four patients discharged at their own request was under treatment three different times, being discharged twice at his own request, but died suddenly while under the third course of treatment, and the autopsy revealed an aneurysm of the aorta which had ruptured into the lower lobe of the right lung.

One of the twelve cases was diagnosed as a weeping aneurysm, implicating the origin of the left carotid, and communicating by a small opening with the left bronchus. The patient on admission expectorated arterial blood, but this soon ceased and he was discharged cured. The writer related the following case, in which, while he was not so enthusiastic as Balfour, he yet attributed the prolongation of the patient's life and his comparative comfort to the use of the remedy:

John H. C., aged forty, a blacksmith, was first seen in March, 1883. Had had attacks of inflammatory rheumatism several years before. In February, 1883, he was attacked with severe pains in the precordial region, and was treated by his physician for rheumatism for some weeks, when Dr. J. P. Ross saw him and diagnosed aneurysm of the aorta. At this time he had a good deal of dyspnea, some hoarseness, and quite a little difficulty in swallowing solid food. When he was fatigued the pains in his chest were excruciating. No tumor was perceptible, although there was pulsation in the upper sternal region, with dullness over the area of pulsation. Two months afterward there was a swelling in the upper sternal region, at the junction of the left first and second ribs, of about the size of a silver dollar. A very slight *bruit* was heard. The voice was very husky, and the difficulty of deglutition had increased, until now the patient could take no solid food whatever. He had become emaciated and was losing strength very rapidly.

He was ordered to lie in bed continuously, and was given fifteen grains of iodide of potassium three times daily, gradually increasing the dose until signs of iodism appeared.

It was truly remarkable how soon, after this plan of treatment was inaugurated, the patient expressed himself free from pain and the distressing symptoms from which he had suffered. He persevered in this way until May, when he said he was so well and so weary of the bed that he would like to sit up. Leave was granted. A few weeks after, the writer was surprised to see his patient walk into his office. He (the man) complained of nothing; he was, however, cautioned against such rash experiments, for his condition was as follows: The continued pulsation of the tumor against the chest wall had produced absorption of a large portion of the manubrium and an inch of the inner portion of the left first and second ribs. Consequently the pulsations of the tumor could be felt through the chest wall at a point where only soft tissues intervened. No *bruit* was discernible.

On laryngoscopic examination, there was found complete paralysis of the left vocal cord. His voice was anserinous.

During all these months he had been taking the iodide of potassium without any disturbing effects until now, when he complained of symptoms of iodism. He was allowed to discontinue its use.

From the date of this office visit, the patient rapidly grew worse. He quickly became emaciated, the dyspnea and dysphagia increased, and finally he died of asthma July 19, 1884, nearly eighteen months after he came under the writer's observation.

The specimen was presented, with an account of the autopsy. On opening the thorax, a large aneurysmal tumor was seen behind the sternum, about five inches in diameter. Friable adhesions of the sac to the sternum were broken up when the sternum was removed. Absorption of a large portion of the sternum and of the left first and second ribs had taken place. The heart and pericardium were normal. There were adhesions between the aneurysmal sac and the left lung, which was pressed upward and backward and collapsed.

The aortic valves were found roughened; the arch of the aorta was dilated, and at the anterior part of the arch, between the origin of the innominate and that of the left carotid arteries, an oval opening, one inch by one and a half, led into the sac of the aneurysm. Through this opening the walls of the aorta were continuous, forming the wall of the aneurysm. The tumor was firm, being composed of coagulated fibrin.

Dr. E. F. INGALLS had been consulted last April by the patient whose case had just been presented in the paper. He found all the symptoms present that Dr. Robison had described. He cited a case of aneurysm of the abdominal aorta that he had treated five or six years before, in which he gave iodide of potassium in large doses, and continued the treatment two thirds of the time for two years. There was cessation of the *bruit* and of the pain, and the size of the tumor had become reduced fifty per cent. He saw the case recently, and there had been no return of the symptoms. He also stated briefly the points of another case, similar in every respect to the first one, that he had treated three or four years before by the iodide of potassium, which soon relieved the distressing symptoms. In a case of thoracic aneurysm that he had treated three years before, twenty grains of the iodide three times daily failed to have much effect, and the patient died suddenly soon after he saw him. The speaker was at present treating a case of abdominal aneurysm in which the enlargement had been reduced fifty per cent. He certainly indorsed the iodide-of-potassium treatment, but would ask how long the remedy could be given continuously before it was likely to have any injurious effect on the mucous coat of the stomach or kidneys? He had treated a case of stricture of the trachea, commencing by giving daily 480 grains of the iodide, freely diluted, for some time, then lessening the dose to 60 grains three times a day for six months. At the expiration of this time the bands of constriction had been absorbed and his patient recovered; but, as a precaution, to prevent any symptoms of it returning, he had the patient continue the iodide in five-grain doses three times a day.

Dr. JOHN BARTLETT cited a case of general chronic bronchitis and asthma, in a man seventy years of age, in which it was stated that the man had had consumption for fifty years, and had been under his observation during the past eight years, during which time he had taken 8 grains of iodide of potassium three times daily (without omitting a day). The man had steadily grown fatter and stronger under this treatment.

Dr. ROBISON concluded by stating that Balfour had abandoned the large doses of the iodide that he formerly gave, and instead now gave 15 or 20 grains three or four times daily for a while; then, if the pulse became quickened or the heart irritable, he stopped the treatment for a time.

The Treatment of Asiatic Cholera as pursued in Southern India.—Dr. H. M. SCODDER read a paper on this subject, in which he favored a particular mode of treatment, based upon nine years' practice in Southern India, during which it was his lot to pass through four epidemics of the plague, he being the only European physician in a town of nearly 50,000 inhabitants. He was at the head of a district hospital, supported by the English Government, and treated a large number of cases. One of the severest of these epidemics occurred during the famine of 1877 and 1878. He was at that time in medical charge of a large, inclosed famine-relief camp, containing over 5,000 persons. Often there were as many as 300 at a time sick with the disease in the hospital sheds, with a death-roll during the height of the epidemic of over 50 per diem. In this camp the writer had opportunities of trying, on an extensive scale, many different remedies and the various modes of treatment, and comparing the results. We will omit enumerating this long list, as also the discussion of the value of the numerous and various forms

of treatment that had been advocated in the East (as was stated by the writer), as our readers are sufficiently familiar with them. With reference to the contagiousness of the disease, the reader considered that cholera was infectious and also *somewhat* contagious, though not highly contagious, or readily communicable by personal association with the sick, as was the case with small-pox and measles. The noxious power of the cholera germ or virus (whether it was Dr. Koch's microbe or something else) seemed to be more powerfully exerted some time after it had escaped from the body of the patient than when it was freshly passed. Careful observation and experience in the epidemics he had passed through, and the world over, seemed to establish this fact. Whether the disease was contagious, or highly contagious, however, seemed to be a vexed question, and remained yet to be decided. His experience in four epidemics, and the careful study of the history of India epidemics, had led him to believe that the attendants, and those who came into frequent and close contact with cholera patients, were somewhat more apt to contract the disease than those who did not.

For purposes of treatment, he divided the course of cholera into the following stages:

1. A period of prodromes, or prodromic stage.
2. A first stage, or stage of diarrhea, or cholérine.
3. A second stage, or stage of invasion.
4. A third stage, or stage of collapse (algid stage).
5. A fourth stage, or stage of reaction.

This last stage might be succeeded by a typhoid condition, or cholera-typhoid state, or the patient might pass directly into a state of convalescence. In the prodromic stage, manifested by lassitude, mental depression, chilliness, nausea, and abdominal discomfort, give ten- or fifteen-drop doses of spirit of camphor, in dessertspoonfuls of hot brandy, every hour or two, but be careful not to allow any considerable quantity of stimulants to be given. When epidemic cholera was prevalent, many were affected by the symptoms just described. If the remedies indicated were promptly taken, he was confident many attacks of cholera would be warded off. It is true that fear often produced these very symptoms. But the spirit of camphor in warm brandy tended to soothe the fears, and dissipate the symptoms, and yet, it did not usually disorder the digestion. So soon as diarrhea supervened, the administration of some preparation of opium, together with aromatics, camphor, and a little chloroform, was urgently called for. Thus, two parts chlorodyne to one of spirit of camphor was a very good combination, thirty drops for a dose, to be repeated as required. Another very serviceable preparation consisted of equal parts of spirit of chloroform, spirit of camphor, laudanum, aromatic tincture of rhubarb, and tincture of ginger—teaspoonful doses were to be given every hour or two, according to the urgency of the case, or until four or five doses had been taken, alternated with an aromatic-sulphuric-acid mixture which might be given to advantage. A popular form was the following:

R Acid. sulphuric. aromat. f ʒj;

Tinct. opii deodorat., f ʒ vi, *vel* f ʒj.

M. S. 20 or 30 drops in water every hour or two.

He suggested the importance of administering these remedies hot, unless they created nausea. The hot water (two or three tablespoonfuls) in which these doses were given might be sweetened if desired. The patient should be required to lie down, and be kept perfectly quiet, covered with heated blankets, and dry heat should be applied to the surface of the body, especially to the extremities, by means of hot bottles, heated flat-irons, etc.

In India, the administration of calomel to any extent had lately been discouraged. One or two small doses might be given if thought best, but not more. So soon as frequent vomiting

began, or the stage of invasion became established, the combinations containing opium which have been mentioned might be discontinued, and either of the following mixtures given instead, in teaspoonful doses at intervals after a spell of vomiting, while at the same time some morphine or morphine combined with chloral should be administered by hypodermic injection, as the severity of the case might demand.

℞ Chloroform.,
Tinct. capsici,
Tinct. cannab. ind., āā, ℥xxx;
Acid. hydrocyanic. dil., ℥xx;
Æther., ℥viii;
Sp. mentha pip., ℥xv;
Syr. sassafras comp. ad f ℥j.

M. S. A small teaspoonful every half-hour or hour. Or

℞ Sp. ammon. aromat.,
Sp. chloroform., āā, f ℥j;
Tinct. capsici,
Tinct. cardamom. comp.,
Tinct. zingiberis, āā, f ℥ss.

M. Give in the same doses as of the other.

A mixture of aromatic powder, gum arabic, and acetate of lead, might also be given alternately with either of these if desired. In any case, mustard plasters should be applied over the stomach and abdomen, but not left on too great a length of time, and, if required, an enema of eight or ten grains of acetate of lead might be given after each evacuation. It was important to bear in mind that some preparation of opium or morphine, or the latter combined with chloral, was the chief remedy for cholera, and the surest agent we could use to arrest the further progress of the disease. When called, therefore, to a case already in the stage of invasion, we should administer morphine, or morphine combined with chloral, hypodermically without delay, in order to get these sovereign remedies into the system as soon as possible. For, if we could arrest the disease before the patient became collapsed, his chances of recovery would be very greatly increased. Caution must be exercised, however, when this form of treatment was pursued, for narcotism was easily induced by repeated hypodermic injections, whereas very large doses of opiates could be given by the mouth and rectum in this disease with comparative impunity. The solution usually employed for injection was, Morphine, gr. ijss. or gr. iv, with chloral hydrate, ℥ijss. or 3 ij to the ounce of water. Inject twenty or thirty minims. The hypodermic use of morphine and chloral was, of course, contra-indicated when the stage of collapse had become developed. During this stage it was most essential that the patient should be kept perfectly quiet and in the horizontal posture. No violent rubbings should be allowed, but it was beneficial to rub the limbs gently with hot oil. To allay the thirst, let the patient suck ice frequently. Carbonic-acid water or simple acidulated effervescing drinks might also be given by the tablespoonful. It was unsafe to allow the patient to drink any fluid whatsoever in large quantities. When the acts of vomiting and purging had become less frequent, and the algid state was well developed, very small quantities of stimulants were useful, but they should be given with great caution, lest vomiting should be provoked. Stimulant enemata might also be given, but, where the stomach had an inverted action, it was often better to inject small quantities hypodermically. Experience taught us, however, that anything like the free use of stimulants in cholera was uncalled for and exceedingly harmful. He had sometimes used small doses of atropine and strychnine by hypodermic injection, which proved apparently effectual in bringing about reaction. Amyl nitrite, by inhalation, might be given a trial, but it seemed to exercise very

little permanent or beneficial effect. Intravenous administrations of milk and salines might be resorted to, but the reaction they induced was not generally of a permanent character, so that many of those who had given this method a fair trial had abandoned it. Of late years, in Southern India, careful experiments had been carried out in reference to the value of impregnating the atmosphere of the sick-room with sulphurous acid by burning sulphur. The result had been that this procedure had been introduced as part of the treatment of cholera. He had on several occasions tried this plan, by subjecting the inmates of two different cholera sheds to exactly the same conditions and the same treatment in every respect, with the exception that in one the atmosphere of the shed was kept impregnated with sulphurous acid and in the other this precaution was omitted. He found that the proportion of recoveries was considerably greater in the sheds where sulphur was used. He, therefore, considered this an important adjuvant in the treatment. The atmosphere should not be so highly impregnated as to cause the patient or the attendants to cough violently. Sulphurous acid thus applied was not only a useful remedy, but it was also believed to decrease the liability of the disease being propagated or contracted by the attendants.

During the stage of reaction great care should be exercised. Vomiting often continued, and the normal absorbing power of the stomach and intestines was but slowly restored. Liquid nourishment by the spoonful should be most cautiously given; well-salted broths and milk, given as hot as possible, and not too frequently, were the only forms of food admissible until the enfeebled stomach showed signs of recovering its tone. Peptonized beef-tea and milk were frequently well borne if carefully prepared, so as not to nauseate the patient. If vomiting persisted the following emulsion might be given:

℞ Acid. carbolic., gr. viij;
Bismuth. subnitrat., ℥ij;
Mucil. acacia,
Aque menth. viridis, āā, f ℥j.

M. S. A teaspoonful every hour or two.

In this stage it was well to let Nature do the work of restoration, and give as little medicine as possible. We must bear in mind, however, that the kidneys must be assisted to resume their functions, and for this purpose mild diuretics, such as nitrate of potassium, should be carefully administered. If fever supervened, it was apt to be of a typhoid character. A combination of iodine and carbolic acid then had a beneficial effect. A popular formula was the following:

℞ Acid. carbolic., gr. ijss.;
Tinct. iodin., gtt. xv;
Aq. menth. pip. ad f ℥iv.

M. S. A tablespoonful every two or three hours.

To relieve restlessness and insomnia, bromide of potassium was often useful.

Dr. G. C. PAOLI said the author of the paper had omitted to mention a prominent English physician, Marshall Hall, who a few years ago, in London, read a paper which excited the interest of the profession in England, because he advanced new ideas regarding cholera, which he compared to the older orthodox theories. There was irritation of the vagus nerve in cholera, and on this theory in the East Indies the disease was treated with hydrate of chloral and nitrite of amyl, but it was not treated with these remedies in Europe. The speaker had seen four cholera epidemics, from 1834 to 1866, and since that time had seen it when it visited Chicago. Of all the remedies to check diarrhoea, the best he had known was sugar of lead combined with opium, in the proportion of gr. ij of the former to gr. ½ of the latter, given as might be thought best. In the col-

lapse stage it was useless to administer internal remedies, because the stomach would not absorb them. The blood was inspissated, and would not circulate freely, and hot blankets were superior to any other external application. If bacilli or bacteria were present in the disease, he believed they were innocent as causes. In fact, any "germs" or "atoms" he believed were imaginary as causes of cholera.

Dr. R. H. ENGERT asked the author of the paper what his percentage of recoveries had been.

Dr. JOHN BARTLETT gave his experience briefly in two hundred and fifty patients with cholera brought to a hospital in which he was attending physician. The percentage of mortality was extraordinarily large. With all the facilities, he expected he would be able to save one half the patients, but only one out of every six recovered. When the patients were brought to the hospital, however, they were in the blue stage, or stage of semi-collapse—partially cyanosed.

Dr. J. H. ETHERIDGE believed the nervous system would in the future be proved to have more to do with the ultimate pathology of cholera than bacilli, which he regarded as an illusion. By using remedies from the first to relax the spasm of the abdominal vessels, to prevent their pouring the watery portions of the blood into the intestinal canal, we should get at the gist of the trouble. When the venous system had become congested, neurotics and other suitable remedies should be administered (perhaps hypodermically) to aid the physiological action of these vessels. Opium, chloral, cannabis indica, and strychnine, he believed, would do this. Years ago the theory was to start the bile, then use astringents; subsequently, however, Dr. Chapman, of London, applied ice-bags to the spine for diarrhoea, to decrease the abdominal vaso-motor spasm, and to aid these vessels in the proper distribution of the blood.

Dr. R. E. STARKWEATHER asked the author of the paper if he thought it expedient for people to retire from the presence of the disease, and whether for a long or short distance. He remembered the epidemics of 1854, 1865-'66, and how the trains were heavily loaded with people leaving the city, for the prevailing idea was to get away from the disease. He was a believer in "cholera sheds"—or building sheds for pestilential diseases—for the care of the people, and instanced how yellow fever had been cared for at Pensacola in this way by the public authorities, which was the most successful method of saving a larger number of lives than any of the methods devised. He believed, from a public point of view, whether in the city or elsewhere, that the public authorities, more so than benevolent societies or organizations, should care for these cases. A large corps of nurses should be available. Health departments had these legal rights, and they should have, readily attainable, an association of nurses—for good nursing was the main thing to be relied upon.

Dr. D. O'SHEA said he had been taught years ago that collapse in cholera was similar to shock from surgical injuries, and that the treatment in both cases should be somewhat similar. Regarding the theory of fright and nervous shock, he cited an instance where he was about to perform a physiological experiment upon a tame rabbit. The animal became frightened, and he remarked to those present that he believed the animal would die from shock, or from being alarmed at the surroundings, and before he proceeded further the rabbit died. As he did not remember having read about the post-mortem appearance of the vessels of persons dying from shock, he concluded to dissect the rabbit, and found the vena cava containing the blood of the body. He cited this as *appropos* of the subject, and he thought it was interesting to show the similarity of the conditions, fright, shock, and collapse from cholera.

Dr. G. NEWKIRK asked if there was not some way by which

the community could be educated through the newspapers, so that the people could forestall these epidemics. He had read in a Jewish newspaper that the Jews in France had not been afflicted with cholera. He did not know that this was absolutely true, but, if it was, he could not understand why they should escape its ravages, or why they were proof against it, unless it was because of their habits or manner of dieting, from instructions they got from Jewish journals.

Dr. SCUDDER, in closing the debate, said, first, as to the percentage of deaths, this varied from 20 per cent. to 90 per cent. In severe epidemics 80 per cent. or 90 per cent. of the cases that were ordinarily seen proved fatal. When cases were seen early, the fatality was much less. To illustrate this better, he stated that in one of the cholera sheds in the relief camp thirty cases were treated by fumigating the premises with sulphur, and over 40 per cent. of the patients recovered, whereas in another shed, out of this number treated (omitting the fumigation), 80 per cent. died. In India, near Calcutta and Madras, where the disease was endemic, the natives would not drink well-water. They drank surface-water or water from tanks near their temples of religion, which they considered sacred, because of this and the reason that it descended from heaven. In contrast to the Indians were the Chinese and Japanese, who used garbage and human offal to fructify the fields and drank well-water. In India these materials were thrown on the surface, or were not covered up, and when the rain, which amounted sometimes to eight or ten inches at night, descended, they drank this surface-water, polluted though it was. He did not see that any benefit would be derived by people running away from a district in which cholera was epidemic. General panic and fright had much to do with predisposing to the disease and with its fatality. In India the poisoning of persons afflicted with cholera was frequent; arsenic was very greatly given, and was largely undetected. To warn the community by newspaper writing was too extensive a topic for him to more than merely mention. If the early, known methods of checking it were resorted to by the natives, cholera would not become epidemic. In India great prejudice existed against European medicines, but not against European surgery. Europeans traveling there were well up in the use of preventive measures. No native of England would travel without a bottle of camphor and a flask of brandy. He would also provide himself with chlorodyne, which was another remedy that was considerably used in India by European surgeons in treating the cholera.

LISTON H. MONTGOMERY, M. D., *Secretary.*

BUFFALO MEDICAL CLUB.

Meeting of August 20, 1884.

Dr. F. W. ABBOTT in the chair.

One Drop.—Dr. JOSEPH W. KEENE read a paper upon this subject. He said:

The present epoch in the history of medicine is pre-eminently characterized by a tendency toward greater precision in investigating and treating disease than has hitherto obtained. For many ages empiricism pure and simple reigned supreme. Diagnosis and treatment alike were based largely on the traditions of the art, and medicine as a science had no existence. Here and there, however, a master mind appeared, with a frequency ever increasing, who rebelled at thus taking for granted the teachings of the elders, and was inclined to inquire the reasons of things. The inevitable decadence of medicine into a mere trade or craft, engendered by adopting, with no effort to test its truth, the teaching of former times, was arrested only by the timely appearance of these men upon the stage. Tower-

ing above the dead level of the mediocrity around them, they stood as fixed points about which the dilute solution of medical thought began to crystallize; or, to better carry out the figure, like those mountain peaks which pierce the higher altitudes, and even in sunshine are crowned with a cloud condensed from the rare atmosphere, so around these commanding intellects the rarefied air of medical thought began to condense into palpable form, and the science of medicine to be evolved.

The process has been slow and marked by retrogressions, but the movement has been steadily onward. A few great advances here and there among the many lesser ones plainly show the onward march of medicine. Dissection of the human body, investigation of post-mortem appearances, vivisection, and the study of the physiological effect of drugs, are prominent among these great advances. Each marks an epoch when medicine, obeying the impetus gained by a multitude of shorter steps, has taken a gigantic stride. And, when retrogressions have occurred, they have been rather the stepping backward of the athlete to gain momentum for his leap.

This tendency toward exactness has evolved the clinical thermometer, the stethoscope, the use of the microscope in diagnosis, and the twofold application of chemistry in investigating disease and in improving our *materia medica*.

Such vague expressions as high or low or moderate fever can but imperfectly voice the conception of the physician. His idea of the conditions may be as accurate as though expressed in degrees Fahrenheit, but he can not satisfactorily convey this impression to another unless he has in his vocabulary terms less uncertain.

The stethoscope differentiates conditions formerly considered identical. The microscope finds in Bright's disease a battalion of maladies, while chemistry lifts the profession toward exactness by segregating active principles from bulky drugs and presenting new products and new combinations.

Even that professional plaything the sphygmograph, a costly and complicated toy, whose tracings record chiefly its own peculiar gyrations and perturbations without rhyme or reason, rhythm or regard to the cardiac impulse except with a large correction necessitated by a multitude of circumstances—and whose value in the diagnosis of cardiac disease is probably coequal with that of the obsolete *planchette* in the diagnosis of mental disorder—even this we can not treat otherwise than tenderly, as evincing a misguided but unmistakable tendency toward precision.

This same tendency is manifest in the improvement in special instruments—the refined armamentarium of the specialist. In extracting teeth, for example, the physician (for some physicians still know how to pull teeth and let blood) is not confined to the tooth-key of former times, but has at command instruments adapted to the contour, shape, and situation of the tooth. In surgery and gynecology, in ophthalmology and laryngoscopy, and all the well-defined specialties, are the results of this tendency markedly exhibited in new instruments devised or old ones improved, thus rendering possible procedures hitherto untried or attempted without success.

In our medical nomenclature and in the recording of cases the same tendency is observable. The attempt is made to name diseases according to their pathology, to the discarding of old names, which are often unmeaning misnomers.

Charts for daily recording and tracing the movement of the bodily temperature, the respiration, and circulation, in so general use, evince the same disposition.

In this general movement toward accuracy it is not surprising that posology should have a share. The researches of the chemist have done much to abolish the huge and nauseous doses of our fathers. Here, again, differentiation is at work. The

active portion of the drug is separated from the inactive or deleterious parts, and thus greater purity of effect is gained by administering a smaller quantity.

In weights and measures employed by druggists the spirit of reform is abroad. The metric system, so invaluable in its decimal simplicity and its adaptability to universal use, is rapidly displacing its cumbersome and ambiguous predecessor—cumbersome in its divisions and multiples, ambiguous in that the same denomination represents different quantities, not only in different nations, but even in the same land. What is a pound? What is an ounce, a grain, a pint? The answer must suggest the absurdity of the system, if anything so chaotic can be called a system. But reform is in progress. The Dispensatory and the Pharmacopœia are gradually sloughing off much that is undesirable, and receiving increments of value. Something of uniformity in preparations, naturally of the same class, now obtains. The scruple has disappeared; the drachm, with its misleading symbol, is treading upon its heels and jostling its departing third. The drop has been abandoned for the minim in stating the dose, so far as the Dispensatory is concerned; and it is lamentable that many of our text-books on *materia medica* and therapeutics still retain the barbarous anachronism. The drop is out of place in our times. Reverence for our ancestors leads us to give the venerable "Signa: One teaspoonful in a wine-glass of water after each meal," just as though a teaspoon or a wine-glass held a definite quantity. Still, as a direction to the patient, these terms, with all their Delphic vagueness, are not so far misleading. Yet a more rational method of exhibiting drugs is already struggling into existence—a method which not only aims at definiteness in the amount to be given, but indicates a reference to the nature and severity of the disease and the stomachic conditions favorable to its ingestion and assimilation, as regards frequency and time of giving it. As active principles become better known and their action better determined, accuracy can be more nearly approximated, and the coarse and crude methods of administration give place to a more intelligent adjustment of the prescription and regulation of the dose.

Simplicity in prescribing is in itself a step toward accuracy. The omnibus prescription, among whose multitudinous ingredients one may chance to influence the given disease, is still far from uncommon. Some of our brethren seem to entertain the idea that the length of the prescription is an index of the depth of their wisdom. So many circumstances may modify the medicinal value of a drug, especially in our vegetable *materia medica*, that it seems desirable to eliminate all modifying circumstances within our power. Many of them, in the present condition of our knowledge, are beyond our control; others are easily reached. If we premise that the true medicinal value of a drug is indexed by the amount of alkaloid or active principle in a given quantity, we shall probably be near the truth. The books speak of various circumstances which render the strength of drugs very variable. The climate, season, time, and mode of gathering and preserving the crude drug—play each an important part in determining the strength of the preparation. When to these factors of uncertainty is added a possible disposition on the part of the manufacturer or dispenser to adulterate his goods, together with an inherent vagueness as to the size of the dose our prescription calls for, and little reliance upon its intelligent administration to the patient, it is no wonder that disappointment often attends medication.

To illustrate: a prescription calls for the compound tincture of cinchona to be given in teaspoonful doses. Some barks have but one twentieth as much medicinal value, as estimated by the quantity of the alkaloids, as others. Bark spent in preparing quinine is also sometimes used to make the compound tincture and the various elixirs. Suppose, now, our manufacturer

sells a cheap or spent bark to the druggist; we will, by courtesy, suppose our druggist to be honest in using the proper weight of this inferior bark in making the tincture; suppose, now, the patient employs, in taking his medicine, a spoon such as we have all seen used for the purpose. It is of silver—a family heir-loom—small originally, and now twisted and battered by the repeated dentition of successive generations, with an occasional indentation from heel or rocker, until its original capacity of perhaps thirty minims is reduced to half that quantity. Suppose, again, that our patient forgets to take his medicine once in three times—a small percentage of forgetfulness, as your experience will testify—how much alkaloid does he ingest per diem? What fractional part of the intended dose really enters his stomach?

Again, a prescription calls for three drops of tincture of aconite root or of nux vomica in a drachm of vehicle. The plant was grown in an uncongenial climate, in unfavorable soil, and in an unpropitious season; it was allowed to mature its seed before gathering; was injured by heat and moisture in drying; the tincture prepared with a due regard to economy; dispensed from a fine dropper giving two or three hundred drops to the drachm; then administered in the spoon above described and omitted in the usual ratio—how much aconitine or strychnine will be ingested?

But it may be argued that no dose can be assigned beforehand as the proper one in any given case; that each case is to be considered by itself and the administration of remedies regulated by the effect produced. This is granted; the very uncertainty as to how much medicine of known strength a given case requires renders precision the more essential where precision is possible. This matter of idiosyncrasy is another element of uncertainty, and a factor which must affect the result. The size of the dose we can easily regulate if we will—at least so far as our prescription is concerned.

But let us premise that all our medicinal preparations are fairly representative of a given amount of alkaloid or active principle; that, on the whole, every preparation is honestly prepared, and varies but little in potency. The advantages of this uniformity of strength may be set at naught by prescribing in a measure so uncertain as the drop. It is well known that drops differ in size, not only in different fluids but in the same fluid under different circumstances. The ordinary practice of dispensing drops from the bottle in which the fluid is kept seems to be the most reliable, in view of the experiments of the writer.

Yet it is impossible to secure uniformity of result, the same bottle giving drops of various sizes according to the amount of fluid it contains, and the rapidity with which they are allowed to flow. With the bottle half full, and each drop allowed to round itself fully, an approximate uniformity is secured. Increase or diminish the inclination, or allow the drops to fall in rapid succession, and their size is modified.

The dropper so generally used by druggists is a snare. In tubes of the same caliber and the same size of orifice, if these two conditions could be secured, the length of the nozzle and of the tube itself, the degree of pressure exerted upon the rubber cap, influence the size of the drop. Capillarity, cohesion, and adhesion, on the one hand, and the ever-varying pressure, the *vis a tergo*, on the other, are factors impossible to adjust with uniformity.

The pipette of the chemist is less objectionable, but here too the same resistances occur, although the pressure, being that of the atmosphere, is constant.

The glass rod gives even greater discrepancies. The drop will vary according to the size of the rod and the length of the flow, the form of the end, and the rapidity of the stream.

The habit of dropping from a cork is, perhaps, the most

reprehensible of all. The size here depends upon whether the cork is wet or dry, upon the length and rapidity of the flow, the inclination at which it is held, and probably upon the quantity of fluid in the bottle.

It is probable that many other influences besides those mentioned act to modify the size of drops. But enough have been cited to show, if proof were needed, the unreliability of the drop as a measure. Indeed, it was assumed at the outset that the main facts were well known to all. It is to lead to a recognition of these facts in prescribing that this paper has been prepared, and the attending experiments have been made, some of the results of which are here presented.

Table showing the variation of several liquids in number of drops in a drachm when measured as ordinarily by physicians and druggists.

	No. of minims in comparison	Dispensing bottle.	Larger common dropper.	Small dropper, moderately flat.	The curved dropper.	Fine short pipette.	Still glass rod, fine stream, dull point.	Coarse glass rod, blunt point.	Wet cork.	Ordinary open tube, without point.
Niagara water....	60	40	130	96	132	204	80	42	28	58
Alcohol, 95°.....	60	100	170	212	326	196	388	138	58	182
Fowler's solution.	60	80	98	118	176	108	232	115	54	58
Tincture of nux vomica.....	60	128	192	260	366	224	294	130	52	64
Tincture of aconite root.....	60	113	184	256	332	214	332	136	56	114
Fluid extract of aconite root....	60	96	184	272	336	292	308	128	66	108

In view of these facts, is it not imperative that we abandon the drop? We will not urge too strongly the adoption of the metric system, so much more exact and so simple, but will, for the present, be content with asking that the profession use the minim instead of the drop.

The paper having been followed by some discussion, Dr. KEENE, in closing, said that he had no doubt the figures in his table would vary greatly with each re-measurement, but that only served to make a fixed standard all the more necessary.

Reports on the Progress of Medicine.

GYNECOLOGY.

By ANDREW F. CURRIER, M.D.

The Homology of the Hymen.—Pozzi's paper ("Arch. de toolol," Apr., 1884) was suggested by two singular cases which appeared in his service at the Lourcine Hospital, in one of which, that of a girl nineteen years of age, there was absence of the vagina, uterus, and ovaries; in the other, a pseudo-hermaphrodite male, there was perineal hypospadias. The studies of the author led him to the following conclusions, which differ materially from those of previous anatomists and investigators. 1. The hymen is an appendage of the vulva and not of the vagina. It is developed from the uro-genital sinus, which also forms the short vestibular canal which constitutes the margin of the vaginal canal. In both of the cases in question there existed a hymen and a vestibular canal, but in neither was there a vagina or a uterus. 2. It is, therefore, by a false homology that the term *bulb of the vagina* has been given to that portion of the vagina which was supposed to correspond to the bulb of the urethra in the male. The spongy bodies of the urethra are not comparable to the *labia minora*. In the author's hypospadias case there were both well-marked nymphæ and spongy bodies, though atrophied, under the form of the bridle or vestibule. The spongy bodies are the result of a special formation along the border of the uro-genital sinus. In the female, and

in a subject of hypospadias, we have, externally, the development of the labia majora; internally, that of the nymphæ. 3. In the female, between the clitoris and the meatus, we find a small bridle, which the author proposes to call the muscular bridle of the vestibule, which is marked with a median groove, and is divided below so as to surround the meatus urinarius. When the hymen is present it appears to be a continuation of this membrane. 4. The study of the balano-urethral bridle, as in cases of hypospadias, shows its connection with the atrophied bridle of the female vestibule. The hymen in the female is the analogue of the whole or a portion of the urethra in the male; it is the bulb in an embryonal condition, non-erectile and membranous, at the entrance of the vestibular canal, a vestige of the uro-genital canal. 5. The analogy of the glands of Bartholin in the female with those of Mery or Cowper in the male is readily traceable. The greater relative length of the ducts in the male glands is noticeable and its object can be readily understood. 5. The muscular bridle of the vestibule in the female is the remnant of the anterior or cylindrical portion of the spongy bodies just as the hymen is the remnant of their posterior or ovoidal portion.

Curetting the Uterus.—Düvelius ("Ztschr. f. Geb. u. Gyn.," x, 1) remarks upon the frequency of the operation of curetting the uterine mucous membrane within the past few years, though its propriety is still questioned by many. Whether it is performed for diagnostic or for therapeutic purposes, its opponents challenge: 1. The possibility of making a diagnosis of the disease of the mucous membrane from the material which is scraped away; 2. The possibility of curing a diseased mucous membrane by the use of the curette; 3. The possibility of a subsequent normal pregnancy. In the author's investigation of this subject he appears to have been able to obtain abundance of material, both from the living and from the dead, and this fact is worthy of notice. The uteri which were operated upon belonged to women between the ages of twenty and forty, excepting in three instances, in which they had passed their fiftieth year. The post-mortem specimens were removed within twenty-four hours after death, and had neither suffered post-mortem changes nor been affected with disease, so far as could be ascertained. The operation was performed upon these specimens in the same way in which it is customarily performed upon the living subject; the specimens were hardened in absolute alcohol, and sections were then made in all directions with a microtome. Microscopical examination showed that in some cases the mucous membrane had been entirely removed, quite to the muscular structure of the uterus, while in others more or less had been left behind. In most of the sections, either deep in the muscular structure or else superficially, the remnants of larger or smaller glandular tubes were seen, which had been torn obliquely. Nowhere was mucous membrane found with its superficial epithelium intact; and, since disease of the uterine mucous membrane could hardly exist without involvement of its superficial epithelium, the first objection of the opponents of the operation is answered by reason of the abundance of the products which may be removed with the curette. In five cases of disease of the uterus the author was able to correctly diagnose the disease by means of small portions of mucous membrane which were removed with the curette. In two of the cases the microscopic examination of the products of the curetting indicated carcinoma of the body, in two malignant adenoma, and in one sarcoma of the mucous membrane. The uterus was removed in all the cases (from the living subjects), and the diagnosis confirmed. In regard to the second objection, two questions become pertinent—(1) whether after curetting of the uterine mucous membrane a renewal of that membrane is possible; (2) whether the new growth, if any, holds

the same relations to the muscular tissue of the uterus as in the normal state, and whether or not scar-tissue is formed. Bearing upon this subject, two patients came under the author's notice who were subjected to repeated curettings with subsequent caustic applications to the denuded surface. The object of the operations was to overcome a tendency to profuse hæmorrhages, and, after they had proved ineffectual, the uteri were amputated. Microscopical examination of the specimens showed the presence of the same histological elements which exist in the normal uterine mucous membrane, but they were abnormally arranged. A cicatrix was not found either in the mucous membrane or on the border between it and the muscular tissue. This result was also confirmatory of the investigations and results of Leopold in the same field. The third objection is groundless not only from observed facts, but also because it has already been shown that no cicatrization of the mucous membrane takes place, and that that membrane is not brought into an abnormal condition by the operation in question. The effect of curetting and the subsequent application of stimulating substances to the surface operated upon is to remove the accumulated secretions, and to remove the superficial or even the deeper layers of epithelium, and no evidence has been brought forward to show that its influence is destructive of function; on the contrary, the author's experience has been that its effect is highly beneficial. Sixty cases of pregnancy were observed in the years 1879 to 1883, in which the women had undergone curetting previous to conception. In some of the cases it was even ascertained that a tendency to abort had been cured by the operation, and the women were enabled to carry their fetuses to term.

Uterine Displacements and their Treatment by Means of Medicated Tampons.—Dr. R. Bell's paper ("Edinb. Med. Jour.," March, 1884) was read before the Edinburgh Obstetrical Society, and offers objections to the too frequent use of the pessary. The views of the author, like those of other gynecologists, have undergone a change upon this subject. The medication to which the tampons (cotton-wool) are subjected is with a mixture of glycerin and alum, and it is maintained that they act (1) as a support to the uterus; (2) as a depleting agent; (3) as an invigorating agent to the uterus and vagina. The condition for which this treatment is especially applicable is retroflexion, and the symptoms which follow such a condition, especially from altered mechanical relations, are too well known to require specification. Prolapsus is also a condition which is amenable to this treatment. Improvement is the rule, by the adoption of this method, and sometimes cure may be effected. In other cases the subsequent use of a pessary completes a cure which has been already begun.

The Relations between Ovarian Cysts and the Broad Ligament.—The subject of the formation of adhesions is one with which every ovariologist is familiar, and, when not too firm nor too intimately associated with contiguous organs, they form no serious obstacle to the performance of ovariectomy. M. Terrillon ("Rev. de chir.," Feb., 1884) considers that those cases in which intimate association is formed by an ovarian cyst with the broad ligament form a class by themselves. In such cases it is not inflammation which causes the unusual or dangerous relations, but the mode of development of the tumor itself, becoming in part infiltrated, as it were, into the broad ligament. Usually it is a single lobe which juts out beyond the pedicle of the parent tumor, and insinuates itself between the two layers of the broad ligament, which do not offer great resistance. In the course of its further development it readily forms organic union with the sides of the uterus, the bladder, the upper part of the vaginal *cul-de-sac*, also with the walls of the pelvis, the iliac vessels and nerves, and even with the ureter. It will there-

fore be useful to remember that a dissection of the layers of the broad ligament will lead one directly to the cyst, and its removal will thus, to a certain degree, be facilitated. Parovarian cysts, which also develop between the layers of the broad ligament, are apt to form strong adhesions with contiguous organs, and their removal is often difficult or impossible. The same conditions may also accompany the development of uterine fibromyomata. The closeness of union which is sometimes found between the cyst, the broad ligament, and the uterus explains the great vascularity of the former, since it is enriched by the vessels of the two latter organs in addition to its proper supply from the ovarian vessels. The author thinks it is well to remember, in examining a case of this kind, that the portion of the original tumor which invades the broad ligament is usually its lower portion. He thinks there is no certain sign by which the condition in question can be made out, particularly in its early stages. A number of indications are mentioned, which are common, however, to other varieties of abdominal tumors. The prognosis in cases in which this complication is present is necessarily graver than in ordinary cases, for reasons which are obvious enough. Complete removal may be impossible on account of the intimate relations with adjoining structures, and the increased liability to septicæmia after an operation, whether complete or incomplete, is to be noted. The operative details will vary according as the tumor has or has not become united with the bladder, rectum, etc. For a full recital of these details we would refer to the author's article.

The Relations of Ovarian Cysts with the Urinary Organs.—The same author ("Ann. des mal. des organes génito-urinaires," Jan., 1884) observes that the fact is very noteworthy that those who are the subjects of ovarian cysts are very apt to be affected with an irritable condition of the bladder. It is equally noteworthy, however, that this rarely develops into a serious complication. When adhesions have formed between the cyst and the bladder or ureters, and the case is presented for operative interference, the question may be a serious one, and will call for the most careful treatment on the part of the surgeon. The functional troubles of the urinary organs from the development of an ovarian cyst may consist either in an exaggeration in the frequency of micturition, or, less frequently, a diminution of desire to perform this act. In the latter case systematic catheterization sometimes becomes a necessity. With the bladder trouble there is very often an accompanying condition of constipation, which becomes more decided with the increasing pressure of the developing tumor upon the rectum. If the tumor encroaches upon the tract of the ureter, serious disturbance in the kidney may result, and Boinet records cases of gastric, pulmonary, and nervous disorders which were traceable to kidney lesions. The ureter is most frequently compressed when the tumor develops between the folds of the broad ligament. In cases in which adhesive attachments to the bladder are formed, ulceration into that viscus sometimes occurs, with evacuation of the contents of the cyst. Such an accident is liable to be attended with considerable pain and shock, but is not, of necessity, fatal. Several interesting cases of this character are recorded. When performing ovariectomy one should always have in mind the possible danger of wounding the bladder, either when it is enlarged and hypertrophied and lies between the tumor and the abdominal wall, or when it retains its normal dimensions, but is attached to the cyst by adhesions upon its posterior wall. Accidents of this nature are usually fatal, and several classical cases are referred to. The author thinks it is a safe plan, in all cases, to evacuate the bladder before performing laparotomy. [Though this is the common belief and practice, it is strongly opposed by no less an authority than Keith, who believes that a full bladder is a useful guide.

See "Brit. Med. Jour.," Dec. 8, 1883, "On Supra-vaginal Hysterectomy," etc.] The diagnosis of vesical adhesions can not be clearly made out in regard to their nature or extent, but the careful and skillful use of the sound will reveal the boundaries and displacements of the bladder, and so put one on guard at the time of the operation. In case the viscus should be wounded, the choice of treatment lies between simple closure of the wound and closure of the wound with suture to the abdominal wall, with the possibility of a fistula resulting. The author finds twenty-five recorded cases of this accident, of which fourteen were fatal. Should the ureters be wounded, the accident, though rare, is an exceedingly grave and embarrassing one, and the possibilities of treatment consist in the formation of an external fistula, or a series of plastic operations such as occurred in the experience of Nussbaum. In Simon's case an injury to the ureter was followed by extirpation of the corresponding kidney. The patient recovered.

Laparo-myomectomy.—Kaltenbach ("Ztschr. f. Geb. u. Gyn.," x, 1) observes that no question in all gynecology is discussed with so much animation as this one. From some cause or other, however, the published reports of cases are too few in number for the establishment of principles concerning the operation. The principles which are applicable in ovariectomy are valuable to a certain extent, but they are not sufficiently comprehensive for the operation which is under discussion. In other words, we must be well grounded not only as to the proper methods, technique, and indications for this operation, but also as to the anatomical relations of the extirpated tumor, and the phenomena which attend the condition subsequent to operation, even after the patient has recovered from the immediate effects of the removal of the growth. Ten cases comprise the author's experience, extending over a series of years. In two of these cases myomectomy was performed, and, in the remaining eight, supra-vaginal amputation of the uterus, the two operations being essentially different both as to difficulty of performance and as to significance. In myomectomy the tumor has little or no pedicle, the uterus is unharmed, or, at least, its cavity is not opened. The treatment of the stump is almost invariably intra-peritoneal, the particular method being governed by the thickness and vascularity of the pedicle. If the pedicle is very thin, excision of the tumor, with subsequent covering of the cut surface with peritonæum, and suturing the divided edges of the latter, is Schröder's plan, and is approved of by the author. In cases in which the pedicle is more than 0.5 cm. in thickness, the best plan is to transfix and ligate, as in ovariectomy, and also to throw another ligature around the mass for additional security. Silk is recommended for ligating small pedicles, and the elastic ligature for large ones. In the supra-vaginal amputation of the uterus, the uterine cavity is, of course, opened, and the pedicle consists of the remnant of the body, if any, and the neck, together with the dependent ligaments. Trunk vessels are in this case divided, and means for the ingress of infectious material are afforded by the canal of the cervix, with its lining of mucous membrane. The author's preference for extra-peritoneal treatment of the stump in this operation is seen in the fact that in all his eight cases this method was used. The stump was held in position by long lance-shaped needles, which rested upon the abdomen; its wounded surface was thoroughly cauterized, and antiseptic applications were constantly used. In some cases the elastic ligature was carried around the pedicle, and in others the latter was transfixed with it. Only one of these eight cases was fatal. Regarding the removal of the ovaries, the author thinks this should form a part of the operation in every case in which the climacteric has not been reached. The indication for operation in two of the author's cases was the great size of the tumor; in four, its rapid

growth, hæmorrhages, peritoneal irritation, and uncomfortable pressure upon abdominal organs; in one, total prolapse of the uterus; and in one, the great discomfort in the pelvic region caused by a tumor in Douglas's *cul-de-sac*. The author is in favor of early operations, to anticipate the discomforts or even serious conditions which may attend the growth of the tumor. The latter is to be removed entire, if possible, thus saving time and diminishing the hæmorrhage. The history of Kaltenbach's patients after their recovery is satisfactory in most respects. The general health of all remained good; in three there was ventral hernia; in one a cervical fistula opened into the peritonæum. These were the most serious accidents which occurred. The prognosis in such operations is now nearly as good as in the removal of any abdominal tumors. The chief dangers lie in the possibilities of hæmorrhage from the extensive development of the vessels at the base of the tumor, in the possible formation of emboli or thrombi, on account of dilatation of the parametral veins, and in anæmia caused by the sudden removal of a firm body from the abdominal cavity. On the other hand, it may be said that the tumors are usually benign in character, that they can generally be removed entire, that there are few adhesions, and that the peritoneal cavity can usually be entirely cleansed. As to the merits of the intra- and extra-peritoneal methods of treating the pedicle, the author's results were obtained with the latter, and he is naturally inclined favorably to a plan which has served him so well. The main improvements which recommend to operators the use of the intra-peritoneal method consist in the isolated treatment of the four trunk vessels, and in the firm suturing of the pedicle. Danger from hæmorrhage and from sepsis is thus, to a great degree, eliminated. The details of the operation do not differ from those which have been recommended by Schröder. With further improvements in the intra-peritoneal method, the author thinks it will ere long supersede the older method. With present experience, both methods have their adherents, and complete justification.

A New Method of Partial Extirpation of the Cancerous Uterus.

The method which Dr. E. Van de Warker ("Am. Jour. of Obstet.," March, 1884) describes is the use of the "potent chemical cautery," in distinction from total extirpation of the uterus through the vagina, and vaginal amputation with supravaginal excision. He asserts its safety and ease of performance as compared with the first of these, while the second is disposed of by the consideration that it is "simply a survival of the antique." [Faint praise for Schröder's operation. For Schröder's statistics, see "Brit. Med. Jour.," Sept. 15, 1883 ("The Vaginal Extirpation of Carcinoma of the Uterus").] The author's plan is as follows: The cervix is amputated at the vaginal junction, and then cut away as high as the os internum with the knife, scissors, or curette, according to the condition of the tissues. The cavity is then packed, not too firmly, with pledgets of absorbent cotton soaked, and then wrung dry, in a solution of sub-sulphate of iron one part, to three of water. Little or no cotton is required in the vagina. The packing must be removed on the second day, and then a solution of chloride of zinc is applied of the strength of five drachms to the ounce of water, or, in some cases, of equal parts by weight. These solutions are also used upon cotton. As a useful precaution, the author recommends a preliminary smearing of all the contiguous mucous membrane with vaseline in which bicarbonate of sodium has been incorporated. The weaker zinc solution is to be used in those cases in which there is only a small depth of uterine tissue remaining; but, if sufficient remains to allow of a deep slough, the stronger solution is preferable. The cotton can be removed in from two to five days, and the slough will follow in five or ten days more. Proper precautions against hæmorrhage

must follow the fall of the slough. Cicatrization is usually accomplished in from two to four weeks. Two interesting cases are narrated, and they are accompanied by cuts which demonstrate the conditions of disease and repair.

New Inventions, etc.

A NEW ABDOMINAL DRAINAGE-TUBE.

By H. MARION-SIMS, M.D.

The accompanying cut gives a very good idea of an abdominal drainage-tube which I had made last winter. It acted so nicely and drained the pelvis so well that I wish to call the attention of the medical profession to it. It consists of a large and a small tube made of hard rubber. The smaller tube is inside of the larger one, running along the posterior wall, and terminating about an eighth of an inch from the bottom. The large tube is perforated on the sides and curved on the top, so that, when in the abdominal wound, the top of the tube projects nearly over the symphysis pubis. The smaller tube is for the purpose of washing out the peritoneal cavity, the water being thrown in at the bottom of the cavity instead of at the top, as in most drainage-tubes. I attach a small rubber tube at B, and force the water to the bottom of the tube C with a Davidson's syringe. At the mouth of the tube A, I attach a larger rubber tube, and, while washing out, the water runs into a bed-pan or any convenient vessel placed in the bed. Where drainage is constant and very profuse, the rubber tube can be long enough to hang over the side of the bed into some vessel placed there. By having the smaller, or washing-tube, project through the dressing on the wound, the pelvic cavity can be washed out without removing the dressing, which will remain dry and clean. This tube is made by Mr. Ford, of Caswell, Hazard & Co., and can be had in three or four sizes.

Miscellany.

THERAPEUTICAL NOTES.

The Nutritive Value of Maltose.—M. Dastre and M. Bourquelot, in a note recently communicated to the *Académie des sciences* ("Progr. méd."), give it as the result of their experiments that maltose undergoes direct consumption when injected into the blood of an animal, without having been transformed by any digestive juice. They estimate its practical value as between that of lactose and that of glucose.

Valerian in the Treatment of Superficial Wounds.—At a recent meeting of the *Société de biologie* (*ibid.*), M. Arragon brought forward a new method of dressing wounds, by which, he declared, their healing was hastened and the pain was made to disappear at once. The method consisted in the application of compresses wet with a decoction of thirty

parts of valerian root in one thousand parts of water. Of fifty patients treated in this way, with only two had benefit failed to result, whether the wounds were lacerated or contused, but it is expressly stated that the treatment is of no avail for deep wounds. In one instance, warm injections of the decoction were used for otitis media. The anodyne effect is attributed to the action of the valerianic acid on the terminal nerves, and an antiseptic influence also is credited to the remedy.

Antipyrine, the new antipyretic alkaloid, has lately been subjected to thorough investigation by Dr. della Cella, at Professor Marigliano's clinic ("Italia Medica"; "Bull. gén. de thérap."), and the following facts have been noted:

Antipyrine presents itself in the form of prismatic crystals, very soluble in water and in alcohol, but less soluble in ether. Its solutions are of neutral reaction. With sulphuric acid it forms a salt soluble in water and in alcohol, but insoluble in ether. Crystallized antipyrine detonates violently when heated with concentrated nitric acid; heated gently with caustic potash, it assumes a reddish color. With oxidizing agents, in the presence of water and heat, it is decomposed into various products, among which derivatives of phenol and of acetone seem to predominate. Its aqueous solution and that of its salts present the following reactions: With chromic acid an orange-yellow precipitate is formed, which becomes liquid with heat. With hypobromite of sodium it forms a white precipitate; on being heated, this becomes yellowish, and little brown drops are seen to separate, having an empyreumatic odor. With Millon's reagent there is a yellow precipitate. With perchloride of iron an intense red color is developed; the liquid is decolorized by impure hydrochloric acid. With iodized iodide of potassium there is an obscure red precipitate. With iodide of potassium and mercury a white precipitate is thrown down. With iodide of potassium and bismuth there is a yellow precipitate verging on orange. With tannic acid the precipitate is white. With picric acid it is yellow. Chlorine water causes no change of color, but, if a current of chlorine is made to pass into an aqueous solution of antipyrine, a solid white substance is seen to separate. Of all these reagents, the most sensitive is iodized iodide of potassium, which gives a reaction with a 1-5,000 solution of antipyrine.

To detect antipyrine in the urine, the latter must first be acidulated with sulphuric acid, in the proportion of about 5 drops to 6 c. cm. of urine, the proportion of the acid being larger if the urine is alkaline. If the mixture becomes turbid, it is to be filtered, and ten drops of the iodic reagent should be added. The presence of antipyrine will be manifested by a red-brown precipitate. This reaction, however, will be more or less marked, according to the time at which the urine has been passed: three hours after the administration of the drug, the reaction is present, but slight; in four hours it is very marked; in twenty-four hours it is still very decided; and in thirty-six hours it is yet perceptible. Sometimes it disappears after four hours, but to return subsequently.

Experiments were made by Dr. Queirolo, an assistant at the clinic, on the general action of the drug and its influence on the arterial pressure and the caliber of the vessels. Antipyrine was given to persons free from fever and to others having fever, to the amount of from 4 to 6 grammes in the course of from an hour to three hours, with the following results:

1. It gives rise to no appreciable general phenomena, although sometimes, in excitable individuals, particularly women, some vomiting is produced.
2. The frequency of the respiratory movements is not affected.
3. The frequency of the pulse is always diminished.
4. The arterial pressure, measured with Baasch's apparatus, is either unaffected or a little increased.
5. The normal temperature is not disturbed.
6. In persons free from fever a very slight dilatation of the cutaneous vessels is produced; in those with fever this dilatation is more marked; it precedes the lowering of the temperature. These researches were made by means of Mosso's plethysmograph.

Its action upon fever, as observed by Dr. Ampugnani, also an assistant at the clinic, is as follows:

1. When 50 centigrammes are given at once, there is generally a lowering of 2 or 3 tenths of a degree [$^{\circ}$ centigrade] in the course of two hours, but this does not last.

2. When a gramme is given at a dose, in the majority of cases the depression begins in an hour, and increases for five or six hours, reaching as much as 3° .

3. If a gramme and a half is given at once, the depression is yet more marked, and after seven hours it still amounts to 2° or 3° .

4. A dose of 2 grammes causes a lowering of from 0.8° to 1.3° at the end of an hour, which increases during the following hours and lasts still longer than before, so that, so to speak, it may blot out a paroxysm of fever.

5. If repeated doses are given, the action is manifested in from six to eighteen hours, and may continue for thirty-six or forty-eight hours or more.

Consequently, phthisical patients who take antipyrine find their fever suppressed not only for that day, but also for the next day, and even the day after, so that, from having been quotidian, the fever becomes a tertian or even a quartan.

Professor Maragliano reserves the results of other experiments for future publication.

The Etiology of Fever.—Dr. S. Davis, of College City, Cal., sends us a communication which we condense as follows: The genesis of fever, says Dr. Read, in the "Journal" of July 19th, remains an interesting though somewhat speculative question. The maintenance of animal heat is to the doctor's mind alike most singular and mysterious. There must, says he, be some inhibitory power in the system for the preservation of this normal standard of warmth. To which I suggest that it would be still more singular if a being so wonderfully made and still more wonderfully endowed was not supplied by the Creator with inhibitory power for both the physical and moral constitutions. For the generation and maintenance of the germinating, invigorating vital heat, we have the wonderful co-operation of the heart and lungs, with the constancy of which under normal surroundings there is no variability or shadow of turning. If the origin of vital heat is still a speculative one, it is a humiliating confession—the profession ever learning but never coming to the knowledge of the truth.

It does seem to me that anatomy and physiology have placed this question of vital heat quite within the compass of professional understanding, on a par with the understanding of at least many other phenomena in nature, sufficiently so at least for all practical purposes of hygiene or therapeutics. The importance of this latter understanding comes in from the well-grounded conjecture, if not even demonstration, that the morbid excitement of the circulation as connected with respiration is the cause of fever. The question, says Dr. Wood or Dr. Read, is whether the rise of temperature, or fever, is the consequence of increased or of retained heat. I answer that it is most evidently from both. In every instance of fever the heat-producing power of the system is morbidly augmented and the heat-radiating power is suspended. The secretions, even the transpiration from the skin, are locked up, and the mouth is dry. Just as Dr. Flint correctly declares ("Practice," third edition), the abnormal action of the heart increases the temperature, giving rise to menal excitement and undue excitability of organs, with augmentation of sensibility and muscular irritability.

A case of fever is analogous to a state of furious anger. Nothing can be done to restore quiet until this insane passion subsides, even at the expense of restraint if necessary. There is the most obvious indication for restraint; for sedation of this cardiac excitement which is the cause of fever.

Diphtheritic Nephritis.—Professor Joseph Fischl read before the German Medical Society of Prague a communication on diphtheritic nephritis. He observed that the epithelium is always swollen and fatty. The lesions are always accompanied by lesions of the stroma. Dr. Fischl has found in nine cases out of ten of interstitial nephritis, especially when subcapsular, that the Malpighian bodies are attacked. He also found vascular lesions, periarteritis, and desquamation of the epitheloid lining. He never observed micro-organisms, although his investigations were conducted with the greatest care, and the most perfect optical instruments were used. A number of microscopic preparations and drawings were shown in support of his assertions.—*British Medical Journal*.

The Question of the Exemption of a Physician's Property from Seizure for Debt.—A New Hampshire physician was unfortunate enough to fall into debt and have judgments entered against him. The creditors naturally tried to obtain payment by issuing execution, and among the articles levied on by the sheriff were the physician's wagon and harness. The New Hampshire law says that such articles as are "tools of a person's occupation" can not be seized and sold under an execution. The physician maintained that his wagon and harness came under this designation, and tried to recover them from the sheriff. The Court, in deciding the question, which is an important one, does not settle the particular case, but refers it to a jury. The legal principles involved are of interest, and we quote from the decision as follows:

"The Court can not say, as a matter of law, that a wagon or a harness is a tool of a physician's calling, and so exempt to all physicians; nor can they say that it is not such a tool. The most that can be said, as a matter of law, is, that it may be a tool of his profession if, in the particular case, it is reasonably necessary for him to use it as a tool. If it should appear that his practice was confined to his office, or that he was a physician or surgeon in a hospital, attending to no cases outside of the institution, or that he was a surgeon on ship-board, or that he went on foot or on horseback, or on the cars, to visit his patients, a wagon and harness would not be exempt under our statute, because they would be of no use to him as tools in his practice. They might be of use to him in other respects, as in going to church, or in carrying his children to school, or in visiting friends, or as a means of recreation and pleasure; but these uses are manifestly not within the legitimate scope of the technical duty of a physician. Not coming within the strict definition of the term tools, and not being reasonably necessary as tools for him in his practice of his profession, they would not be tools within the meaning of the statute, and so would not be exempt as such. But if it should be found that the physician claiming the exemption could not practice his profession with reasonable success without a team with which to visit his patients; that he was located in a country town, for example, where it was necessary for him to ride a large part of the time in order to accomplish anything professionally, a wagon and harness might properly be found to be reasonably necessary for him as tools of his occupation. But the finding would be one of fact, so far as the reasonableness of the use is concerned; and it could not be said that these articles are exempt to every physician, or to physicians generally, but only to the debtor in the particular case. If there is any doubt whether an article claimed to be exempt from attachment is a tool under the statute, the question should be submitted to the jury whether its use as a tool by the debtor in his business is reasonably necessary. If it is, it is exempt; otherwise, it is not exempt."

The Management of the Placenta.—In a paper read before the Ohio State Medical Society ("Columbus Med. Jour.," Aug., 1884), Dr. J. C. Reeve, of Dayton, expressed his views as follows:

Although, over and over again, in lists of cases of inversion "pulling at the cord by the midwife" is given as the cause, I believe that in many cases this is pure assumption, and that in the majority it is gross injustice. The annals of obstetrics show that ignorant midwives have done all sorts of outrageous things, but, when it comes to inverting the uterus by pulling at the cord, the physician is certainly more likely to do it than a midwife. He pulls in the axis of the straits of the pelvis, of which she knows nothing, and a large portion of the force she applies is expended in drawing the cord against the pubes. I presume there are few members here who have not been called to cases where the cord has been torn off in attempts to deliver the after-birth, and all know how fragile it is and how easily it gives way. There must be a favoring condition of the uterus, a state of complete inertia, as the prime factor in the process whenever traction on the cord has been effective in causing inversion.

If this serious accident of childbirth is to be referred to modes of delivering the placenta, I take the ground that it is quite as likely to result from the present accepted mode—Credé's—as by pulling at the cord. Given the state of inertia of the uterus just referred to, which is one of the conditions for inversion, and pressure on its external surface can not fail to produce a dimpling or depression of the fundus which then, by the well-known process, becomes complete inversion.

Possibly I shall be indicted for intimating that a process so generally followed and so universally lauded may not be perfect. But I do not hesitate to say that Credé's method can not always be carried out; it is not always possible to grasp the uterus and apply pressure generally over its surface, or over the major part of it; and I take the position that, if the pressure is applied to a portion of the uterine globe, it is liable to produce depression of the walls, the initial step of inversion; that if Credé's method is unskillfully performed it is as likely to cause disaster as is delivery of the placenta by traction. Recently a good many voices have been heard to the intent that Credé's method is not perfect, and there are cases on record showing that it has been effective in producing uterine inversion. In a debate at the London Obstetrical Society Dr. Edis called attention to the increasing frequency of uterine inversion, and stated his belief that it was due to the employment of too much or ill-directed force in the expulsion of the placenta according to Credé's method. Spiegelberg recognizes expression of the placenta as a cause of inversion, and gives references to cases. Mundé, in this country, has expressed his dissatisfaction with Credé's method. Many of Credé's countrymen have written against it. And I must add that, when Credé states that in two thousand labors "the average duration of the third stage was only four minutes and a half," he writes down his own condemnation. This is not nature. Smellie recognized the truth. For the safe delivery of the placenta we must wait a while; allow the uterus a time of rest; give its fibers time to undergo tonic contraction, and its ganglionic centers time to gather power for the final effort. With clear recognition of the physiological process we can render intelligent and efficient aid in pathological conditions.

No teaching as to the delivery of the placenta can be scientific which does not direct a consideration of the character of the preceding labor, and as the character of labors varies, so must the management of the third stage. If the pains have been frequent and energetic and the birth of the child rapid, the placenta may be delivered very soon; if the labor has been tedious and delivery slow, or if the uterus has been exhausted by violent and long-continued effort, time must be given for the recuperation of its contractile force and nervous energy.

Recent Lyons Theses.—"F Lyon médical" gives the following list of these presented to the faculty of that city during the months of June and July, 1884: No. 214, Corelysis—A Clinical and Critical Study of Förster's Method, by M. G. Souquière; No. 215, The Mode of Action of the Forceps, by M. L. Thassard-Haste; No. 216, The Treatment of Puerperal Fever with Cold Baths, by M. P. Chabert; No. 217, General Pseudo-paralyses, by M. L. Blache; No. 218, The Treatment of Pneumonia with Cold Baths, by M. C. Goumy; No. 219, An Experimental Study of the Virus of Puerperal Septicæmia, by M. C. Truchot; No. 220, A New Process of Mixed Anæsthesia, by M. F. Colombel; No. 221, Choreiform Movements in General Paralytics, by M. J. Sage; No. 222, The Resorption Fever of Phthisical Persons, by M. F. Rolland; No. 223, The History and Development of Legal Medicine, by M. C. Masson; No. 224, The Normal Movements of the Eyelids, by M. A. Domeek; No. 225, Vaginal Hematocele, by M. L. Roché; No. 226, Two Cases of Hystero-epilepsy, by M. C. Burgat; No. 227, The *Bruit de galop*, by M. P. Charvet; No. 228, *Asphyxia locale* of the Extremities, by M. J. Eparvier; No. 229, Indirect Fractures of the Ulna and Fractures of the Radius by Torsion, by M. F. Brossard; No. 230, Anal Fistula, by M. N. Franco; No. 231, Vaccinal Contaminations, by M. E. Jossarand; No. 232, Sprain of the Foot and its Treatment, by M. A. Vaqué; No. 233, Acute Delirium of the Typhoid Form, by M. A. Rousset; No. 234, The Influence of Prostatic Hypertrophy on Strictures of the Urethra, by M. P. Liénard; No. 235, The Cholera of 1884, observed at the Toulon Naval Hospital, from June 18th to July 18th, by M. M. Randon; No. 236, Cancer of the Pancreas, by M. J. Vernay; No. 237, Rectal Etherization and its Dangers, by M. P. A. Héron; No. 238, Precocious Cancer of the Stomach, by M. M. Mathieu; No. 239, Hydrarthrosis of the Knee after Fractures of the Thigh, by M. J. Barudel; No. 240, Complete Deflection of the Course of the Intestinal Contents in the Treatment of Cancer of the Rectum, by M. A. Lagauite; No. 241, The Therapeutical Use of Hydrochlorate of Kairine, by M. E. Drély.

Original Communications.

RECENT STUDIES ON
THE THEORY OF THE MICROSCOPE,
AND THEIR PRACTICAL RESULTS AS REGARDS THE USE OF
THE MICROSCOPE IN SCIENTIFIC INVESTIGATIONS.*

By R. HITCHCOCK,

NATIONAL MUSEUM, WASHINGTON, D. C.; FELLOW OF THE ROYAL MICROSCOPICAL SOCIETY.

Few who are not constant readers of the literature pertaining to the physics of the microscope are aware of the great advances that have been made in the knowledge of the microscope as a physical instrument, and of the correspondingly great progress in the construction of the optical part due to such knowledge that has been made within the last ten years. Nevertheless, the subject is of great importance to every observer, and, although to make it clearly understood it should be treated mathematically, in a manner which the author of this paper would not undertake, it has seemed desirable to present the salient features of our knowledge of the microscope as a physical instrument in a manner to indicate fairly well the bearing of recent researches upon the scientific use of the instrument. To do this for the benefit of the biologist, histologist, and others whose time and interests have been too much occupied with their work to study the merits of different objectives and accessories, makes it advisable that we should begin with some explanations with which many here present are familiar.

Probably every observer of experience has a more or less clear recollection of the long and bitterly-fought battle which raged among microscopists not many years ago about angular aperture. There were advocates of wide or high angles who believed the value of an objective increased with the angular aperture, and this view was advocated with all the steadfastness and vigor of such faith as would move mountains had it been properly directed to that end. On the other hand, there was a more conservative, but none the less vigorous, party totally opposed to these views. The bitterness with which this controversy was carried on at times, year after year, is a blot upon the literature of the subject. But the differences of opinion arose partly, no doubt, from stubbornness and erroneous observation, but mainly from want of knowledge concerning the subject. There was no recognition of a standard by which the value of an objective could be determined. It was a controversy, in fact, between those who believed in tests by resolving fine markings on diatoms, etc., and those who believed in clear definition of such objects as the podura scale. To be sure, other elements entered into the controversy, as, for instance, the question of the proper measurement of the angle of aperture; but the great question of interest to workers with the microscope was, What is the best objective for use, a wide or medium angle?

At the present time this question can be answered; but a few years ago it was purely a matter of opinion. The

theory of the microscope then generally accepted was erroneous. The functions of angular aperture were, in theory, entirely misunderstood.

Let us endeavor to understand the subject in the light of recent investigations, for which we are mainly indebted to Professor Dr. E. Abbe, of Jena, who has established a theory of the microscope, based upon experimental and mathematical investigations, which, in its essential features, if not throughout, seems as firmly established as any theory in optical science.

When an object marked with fine striæ—such as a diatom-shell, for example, or a glass plate ruled with lines, and having the markings separated by spaces as minute as a wave-length of light—is illuminated in the ordinary way under the microscope, it is obvious that the light will be decomposed and a diffraction spectrum formed, precisely as in the case of Professor Rowland's beautiful ruled plates. Considering any single ray from the mirror, when it reaches such an object it will be turned from its direct course and pass off at an angle, forming a microscopic diffraction spectrum. This spectrum may be seen and examined in a manner to be described further on. First, I must ask you to recall some old experiments given in text-books on physics. I refer to the interference bands of diffraction spectra. You will remember how the waves of light, when their vibrations come together in a certain manner, interfere with each other and produce lines of darkness due to overlapping spectra. I can not go further into this subject here. The principle has been brought before you, and that is sufficient for the purpose in view. It must be clear to any one that, if the light is thus turned from its course and decomposed, it can not go on to form an image in the microscope as it was supposed to do according to the old theory of the microscope. It was then supposed that the microscope formed an image precisely as figured in works on physics in use at the present day, and in the same manner as the telescope. Large objects, and outlines of objects generally, are imaged in this way; but, obviously, this can not be true of the fine markings closer than a wave-length of light.

Let us see what becomes of the diffracted rays forming the spectrum. Place a dry-mounted specimen of *Pleurosigma formosum* under a microscope, and examine it with a half-inch objective. When the markings are distinctly seen, remove the ocular and look down the tube of the microscope. There will be seen the diffraction spectra just above the objective. Then put on the ocular, and with a hand-lens examine the light which issues from it in the same way. There the same spectra will be found again. I will not attempt to explain how it is that these spectra are combined in the image we see to produce the appearance of lines or dots, as the case may be. The subject is too intricate to be easily understood; but the fact must be taken, upon the authority of Professor Abbe and others, that the power of a microscope to define or resolve minute markings is absolutely dependent upon its capability of gathering in and properly disposing of the spectra produced by the object.

We will now go a step further in the consideration of the formation of the spectra. You are all familiar with the

* Read before the American Association for the Advancement of Science, September 5, 1884.

fact that diffraction spectra are of different orders—that is to say, we have several secondary spectra produced, one beyond the other, more or less overlapping each other. So it is under the microscope, and the number of secondary spectra will depend upon the fineness of the markings of the object and the length of the vibrations of the light (which will vary in different mounting media). It scarcely need be said that, when the object is so finely marked as to produce two spectra, the microscope must take in both of these to reveal its finest lines, and, if the object produces three spectra that are essential to show its structure, the microscope must take the third in also. Since the rays forming the second and third spectra are diffracted, respectively, farther from their courses than the others, it is obvious that the capability of an objective to take them in depends upon its angular aperture—the angle of light which it will take in under the conditions of experiment.

We now come to an interesting and exceedingly important fact concerning the appearances produced by diffraction spectra. If an objective is incapable of taking in the spectra necessary for a true portrayal of the object, it may, nevertheless, be made to give an image which, to all appearances, is true, and would not give any evidences of further details to be brought out by other lenses. It may also happen that, by proper manipulation, an objective capable of showing the finest markings of an object may be made to show the object clearly defined with only one half the true number of markings—the structure appearing to be much coarser than it really is.

It may be asked how it is possible, in view of such facts as these, to place great dependence upon the microscopical appearance of objects; how are we to be sure that the resolutions we see of fine markings are true? How do we ever know that the objectives we use are capable of showing true structure, or that our manipulation of them has given us the true and not the false?

It is not my purpose to enter upon a discussion of these questions. It would require too much time and involve a more full discussion of the theory of the microscope. Sufficient has been said to place the observer on his guard against errors of this kind. In some cases structure can not be known from microscopical examination.

We now come to the consideration of angular aperture. The cone of rays radiating from the focal point of the objective to the periphery of the front lens is the angular aperture—the angle of light it will receive.

Suppose an object to produce a diffraction spectrum just beyond the range of a certain objective working in air. Interpose a refractive medium like glycerin or water between the object and the front lens. The rays which before were beyond the range of the objective are now brought, by refraction, to a smaller angular deviation, the spectrum is taken up by the objective, and the markings are resolved. We can thus understand the action and the advantages of immersion objectives. It has long been an axiom with microscopists that resolution of fine lines is dependent upon angular aperture, but in this case the immersion medium has materially lessened the angular aperture, yet the resolving power of the lens is increased. Nevertheless, the angu-

lar aperture has been shown, under the conditions previously mentioned, to determine the resolving power. The apparent discrepancy here is easily explained, although it has caused interminable confusion in the past. The explanation in brief is this: Angular apertures can only be compared under the same conditions. Thus, angular apertures of objectives working dry, or of objectives working in the same immersion fluids, can be compared among themselves, but those of one class can not be compared with those of the other class. Thus, a dry objective of 157° will resolve no more than one having an immersion angle in water of 94° , or in oil of 80° .

It will be seen that such comparisons are apt to be very confusing, and for this reason the term angular aperture might better be entirely discarded. A perfectly satisfactory method of designating the resolving power of an objective has been adopted by microscopists on the recommendation of Professor Abbe. It is by determining the "numerical aperture." In highly refractive media the undulations of light become much shorter than in air, and, as the capabilities of the microscope are dependent upon the wave-lengths, it is obvious that dense media for mounting add to the resolving power. Moreover, the visibility of an object is affected by the relation between the refractive indices of the object and the mounting medium. The more these differ, the more visible the object will be. But time would not permit, even if it were desirable, a longer discussion of the optical action of mounting media of different refractive powers. Suffice it to say that Professor Abbe has shown, both by experiment and calculation, that the true aperture—distinguished, when desirable, as the numerical aperture of a microscope objective—which is the capacity of the objective to receive rays from an object to form an image, is the ratio between the focal distance and the diameter of the back-lens of an objective. This ratio will depend upon the refractive index of the medium of immersion, and is expressed by the product of the index of refraction multiplied by the sine of half the angle of aperture for the particular immersion medium employed. This is expressed by the much-used formula $n \sin. u$.

Since the resolving power of a microscope depends upon its numerical aperture and upon the wave-length of light, it must be clear to any person that, when the markings of an object are so exceedingly minute that they can no longer produce the diffraction spectra necessary to form a correct image, they are beyond the range of microscopic vision. It will also be understood that, since it is a matter involving the wave-length of light, the use of optically dense media to reduce the amplitude of the vibrations of light adds to the resolving power of the microscope. Likewise, finer details can be made out with blue rays than with red, and structures finer than the eye can see may be photographed.

The limit of resolving power has been calculated for different media and apertures, ranging from 1.52 —which is, theoretically, the highest attainable with an immersion medium of refractive index 1.52 , since it corresponds to 180° of angular aperture in that medium—down to 0.50 , and a table giving the figures is regularly published in the "American Monthly Microscopical Journal." The range of resolving

power at present attained in practice scarcely exceeds 112,000 lines to the inch,* which should, theoretically, be attained with an aperture of 1.16, but the optical construction does not permit of the attainment of theoretical perfection. The highest numerical aperture to be obtained from the opticians is about 1.43.

Before entering upon another, and perhaps more generally interesting, part of the subject before us, I would wish to draw your attention to a fact that can not be too strongly brought forward. From what has been said concerning the formation of images of minute markings by the decomposition of the light and the production of spectra, it will be readily inferred that whatever objects will form identical spectral images, no matter how different the structure of the objects themselves may be, their appearance in the microscope will be the same. As a single example to illustrate the practical bearing of this fact, we may consider the resolution of any finely marked diatom. By changing the illumination, the dots may become lines, or the lines in some cases may be made to appear twice as close or half as close as they really are. Time does not permit me to enlarge upon this subject as I would wish, but it has an important bearing upon our interpretation of the revelations of the microscope.

We have already seen that there is a theoretical as well as practical limit to the power of a microscope to separate fine lines. This limit is determined, first, by the numerical aperture of the objective, and, secondly, by the magnifying power of objective and ocular combined, which in every case must be sufficient to separate the lines in the image until they subtend an angle large enough to enable the eye to distinguish them. This amplification attained, supposing the resolving power of the objective to be tested to its highest limit, no further amplification can possibly reveal any finer details in the image. Nevertheless, a slight increase is desirable to render the details more distinct, as all who work with delicate test-objects well know. There is, therefore, a well-defined relation between numerical aperture and amplification which renders it possible to define the limits of adequate and desirable amplification for every objective. A recognition of this fact will show that the use of oculars of excessively short focal length, or high power, must be extremely limited in scientific investigation.

Passing now from the microscope itself, what has been said will enable us to appreciate the value of certain accessories for illuminating objects under investigation. It was not many years ago that the most valued, and likewise the most costly, apparatus for illuminating objects for high powers was the achromatic condenser, made very much like an objective, with a small front-lens, and a complicated system of diaphragms beneath. Fortunately, such costly appliances are no longer necessary, and, although achromatic condensers are still made, their form is quite different from those in general use ten years ago.

For the scientific student there is no device more generally useful than the Abbe illuminator, with its full comple-

ment of diaphragms. It is not strictly achromatic, but that is of no consequence. It is not costly, compared with other forms, and is well adapted for universal use. It gives the observer complete control over the light, and is a great aid in all delicate observation. I feel like dwelling longer upon this subject, to urge the use of this apparatus upon our scientific students. I am aware how many of them affect to despise all accessories. It is because they do not know their value. It will not do to say such things are of no use merely because they have not felt the need of them, for such persons do not know of what they speak. The true student of science should be quick to take advantage of every aid afforded by the optician's skill; as to the practical value of the Abbe condenser there can be but one opinion.

Reasoning from what has been said concerning the theory of the microscope, it will be obvious that a careful management of the illumination is essential to the best results in microscopical work. The mirror alone can be made to do almost everything, but it must be handled with far more skill than most scientific observers possess. They do not acquire such skill in the work that occupies their attention, and for that reason they fail to use the microscope to the best advantage. Not only is this true, but their experience as observers is often too much restricted, and I have known persons of undoubted ability in certain lines of work to make surprising blunders, due to misinterpretations of images in the microscope, which no person of broader experience would make. It is a great advantage to any observer to be able to resolve fine test-objects, as such work not only gives command over the instrument, but teaches one how to get the clearest definition and how to avoid or detect false appearances. The use of the Abbe illuminator greatly facilitates the management of the light, and often brings out details of structure very clearly that would otherwise be very easily passed without notice.

The use of polarized light in connection with the microscope is of great importance to the mineralogist, who is enabled to study the optical properties of minerals as they occur in rocks in microscopic quantities. The ordinary arrangements for polarized light serve well enough for such purposes, and for the ordinary requirements of the microscopist. A far more elaborate and delicate apparatus for studying the optical properties of minute objects is the polari-spectro-microscope of Rollet,* or the spectro-polarizer of Zeiss,† which serves the same purpose and can be attached to the ordinary microscope. Both these instruments consist of a polarizing prism, a dispersing prism to form a spectrum of the polarized light, and a plate of selenite. The different colors of the spectrum can be made to traverse the field of view in succession. The mica produces dark bands of interference, the position of which depends upon the thickness of the selenite. An object possessing the slightest property of double refraction, such as a piece of muscle, for example, when placed in one of the dark bands, adds to the thickness of the selenite, and in certain azimuths becomes luminous in the dark band. These instruments are

* One hundred and twenty thousand has been alleged, but we are not satisfied with the evidence in support of this rather improbable feat.

* "Am. Monthly Micr. Journ.," iv, 168.

† *Loc. cit.*, iv, 174.

undoubtedly the most delicate means we have of studying the optical properties of minute objects, and their value is enhanced by the ease with which the wave-lengths of the light used can be measured. The relation between resolution of fine lines and the wave-length of light makes it obvious that with blue light finer details can be seen than with light of lower refrangibility. Also that finer details may be photographed than can be seen. The usual method of obtaining monochromatic light is by the use of a colored glass or liquid interposed in the path of the rays. A more elaborate device has been constructed by Mr. Zeiss. In this, two prisms are mounted, as for a spectroscope, in such a manner as to throw a spectrum upon the object under the microscope, which may then be examined in light of any color.

REPORT OF A CASE OF STRICTURE OF THE ŒSOPHAGUS.*

By RUFUS P. LINCOLN, M. D.

The patient whose history furnishes the subject of this report was fifty years old, a native of Hayti. He arrived in this city the last of June, 1883, and was referred to me by Dr. Otis. He was then suffering from aphonia, a moderate amount of dyspnoea, and dysphagia, with regurgitation of food into the nares, and vague pains in the neck, sometimes shooting up to the ears, and in the upper part of the chest.

These symptoms, according to the patient's account, had been present, with varying degrees of intensity, during the previous eighteen months.

He had spent about half his life in Europe—always a good liver, he was temperate in all things but the use of tobacco. For many years he had smoked from fifteen to twenty strong cigars daily, occupying the interval of smokes with an occasional pinch of snuff.

In the summer of 1882, while traveling in Switzerland, in consequence of exposure to a cold rain at night at a railroad station, he contracted a severe attack of rhinitis, pharyngitis, and laryngitis. Skillful treatment in Paris soon relieved him of the principal symptoms of this attack.

He at this time experienced the first symptoms of obstruction to breathing, which was then pronounced asthma. There was also some difficulty in swallowing. He was never afterward entirely free from this "ball in his throat," as he described it.

On arrival at Cape Hayti, in September, 1882, his disease was pronounced "syphilitic laryngitis," and he was put on a course of four grammes of the iodide of potash daily. He was also treated locally, by means of the brush, with tannin, alum, and nitrate of silver, one after the other. He insisted that this treatment always aggravated his distress, and kept the pharynx looking like "raw beef-steak." His voice gradually became hoarse until, March, 1883, when he was aphonic, and much troubled by choking when he attempted to swallow anything.

On inspection of the neck, there presented anteriorly a

general fullness, extending from the cricoid cartilage down to the sternal notch. The thyroid body was enlarged, and on either side, extending under the edge of the sterno-cleido-mastoid muscles, there were enlarged glands that were movable, one on the right side near the clavicle being painful to pressure, and more firmly fixed than the others.

On examining through the mouth, the pharynx was found congested, the epiglottis red and thickened, the whole larynx stenosed, especially on the left side, where the arytenoid was so much hypertrophied as to be immovable on attempted phonation, thus preventing action of the corresponding vocal cord, while the right approximated the median line.

On account of the extreme sensitiveness of the pharynx and larynx, the œsophagus was not explored with sounds, but an obstruction was readily located on auscultation while the patient swallowed water, opposite the seventh cervical and first dorsal vertebræ. With care, liquids and finely masticated food could be swallowed, though this often induced coughing and forcing of food into the nares.

The patient was at this time under observation about a month, during which time there were two attacks of a chill, followed by fever, repeated daily for three days, and yielding to full doses of quinine.

The stenosis of the larynx improved, so that the voice was normal and respiration no longer embarrassed; swallowing was also better performed, so that food other than liquids, if thoroughly masticated, was freely taken. The pharynx and epiglottis resumed their natural appearance; exteriorly the general fullness of the neck and the thyroid gland, above referred to, had subsided, the enlarged cervical glands, however, being but little diminished in size, though they were perceptibly softer, smaller, and no longer tender to pressure.

The patient was again seen in September, he having spent the interval comfortably, gaining flesh and strength, in Richfield Springs. There had been, however, within a short time a gradual recurrence of the former symptoms, except that the voice was unchanged. During the last week in September the quantity of food swallowed amounted to scarcely anything, and the respiration became alarmingly difficult (though there was no aphonia), so that the skin was somewhat cyanosed, and there was some delirium. These urgent symptoms in respiration yielded after two or three days, but not so the obstruction to deglutition. Attempts to pass œsophageal sounds and bougies, even the smallest, were not successful in penetrating entirely through the stricture, and were always followed by much inflammatory reaction. Dr. Otis was present and participated in several of these efforts.

November 3d I passed a metallic sound entirely through the stricture, but so much inflammation followed that the attempt was not repeated till November 13th, when Dr. Weir was present and passed a bulb-pointed catheter, size No. 22, with little difficulty. One goblet of milk-punch was injected into the stomach, and an hour later this was repeated, the catheter remaining in the œsophagus in the mean time.

The pulse at this visit was 110, and there was no rise in temperature. After chatting an hour, the patient went to

* Read before the American Laryngological Association, May 13, 1884.

sleep and slept undisturbed three hours, till 12 P. M. On waking he was much agitated, and complained of palpitation and rapid breathing. I saw him at 5.30 the following morning, and found the pulse 160, and the respiration 60 and panting. Some whisky and water was swallowed, and an enema of beef-peptonoid with whisky administered, but the patient expired about 9 A. M.

During the last six weeks of his life the patient was chiefly nourished by three nutrient enemata daily, inunctions of cod-liver oil, and hypodermic injections of cod-liver oil, amounting to from a half ounce to one ounce daily.

An autopsy was made, with the assistance of Dr. C. D. Seudder, six hours after death. Rigor mortis well marked. Emaciation not extreme. Of the organs examined, the heart, lungs, stomach, and liver appeared normal. The larynx, trachea, and œsophagus I here exhibit.

Specimens of the morbid tissues were sent to Dr. Heitzman and Dr. William H. Welch, both of whom unite in diagnosing medullary cancer. The following is the substance of Dr. Welch's report.

Cancerous deposit found in the anterior wall of the œsophagus, near its commencement, and the infiltration slowly spread, until about two inches and a half of the surface were involved. This deposit spread laterally, and by contiguity the deep portion of the œsophageal wall was also infiltrated with cancerous matter, which subsequently affected the posterior and lateral walls of the lower part of the larynx and upper part of the trachea, giving rise to the numerous nodules seen there; these have coalesced to a great extent, especially posteriorly. The cervical lymphatic glands shared in the disease, as is usual with cancer, and infiltration took place into the tissues surrounding them, involving the vagi nerves.

The dysphagia and aphonia were produced by local cancerous material in the œsophagus, larynx, and trachea, and by the diffused cancer that involved the laryngeal and œsophageal branches of the vagi. Death finally resulted from affection of the cardiac branches by the same cancerous deposit.

DISCUSSION.

Dr. ROE—I have left a pharyngeal tube permanently in the œsophagus of patients suffering from cancerous stricture, in one instance having allowed it to remain for over one hundred days without removal. Since other than malignant cases have been mentioned, I will refer to two cases in which I have performed internal œsophagotomy with success. Several more, in the hands of other operators, are on record. In my first case the stricture originally was of large size, and was kept open for over a year by the passage of bougies. Finally, however, dysphagia became so serious that I performed internal œsophagotomy. The patient was able immediately to swallow without difficulty. Bougies were passed for about four months, but, no tendency to recontraction having been shown, their use was discontinued. The operation was done about eighteen months ago.

The other case was that of a woman, and the operation was successful. Where appropriate, I think internal œsophagotomy should always be preferred to gastrostomy. I believe there are only two or three patients now living who have survived gastrostomy as long as one or two years.

Dr. KNIGHT—I think that before resorting to gastrostomy

we should bear in mind the fact that the patient must afterward lead a very miserable existence, and that, in the case of malignant disease, life could be prolonged but a short time any way. I would not resort to the operation unless there were some special reason for prolonging life.

Dr. DONALDSON—I can not think it necessary to resort to so serious an operation as gastrostomy in cases of stricture of the œsophagus from adhesive inflammation resulting from caustic fluids. In the case of a child, two years of age, who swallowed concentrated lye, and in whom, two weeks later, it was found that there were two strictures of the œsophagus—one about the level of the seventh cervical vertebra, the other near the cardiac orifice of the stomach—soft œsophageal bougies were introduced, more or less continuously, for over two years, the œsophagus being thereby kept open. In another similar case I would keep the œsophagus open by allowing a perforated tube to remain in, as has been done by others. Of course, no force should be used in introducing the tube, for fear of rupture.

Dr. INGALLS—I consider the plan suggested by Dr. Donaldson a good one in some cases, but it is not always free from danger. I recall the case of a child who swallowed caustic, resulting in stricture of the œsophagus, for which a surgeon passed a bougie several times. On one occasion the bougie caused considerable pain, and, the pain persisting, I was called late in the day, and found the child suffering from pneumothorax. Death took place the next morning, and at the post-mortem it was found the bougie had made a false passage, and entered the left pleura.

Dr. DALY—I hope that the next time Dr. Lincoln has occasion to treat a case of this kind he will undertake the operation of gastrostomy, which has been done so successfully in Germany. Some two or three cases of stricture of the œsophagus, due to the swallowing of caustic potash, or other cause, have fallen under my care, and I have regretted that I have not had an opportunity to perform gastrostomy, but I would not hesitate to do the operation in the future.

In closing, Dr. LINCOLN said—In reply to Dr. Roe's criticism that bougies should have been left *in situ*, it should be borne in mind that any attempt at interference with the œsophagus, at least sufficient to pass a sound, was always followed by great inflammatory reaction; moreover, there was a prompt improvement that attended the soothing treatment at first instituted which seemed to justify its continuance.

As to Dr. Daly's suggestion that gastrostomy might have been tried, I wish to say that, while the statistics of operations so far reported give but little encouragement for adopting this method in any case, certainly the sequel in this case shows it would have been useless, death having been due to implication of the cardiac branches of the vagi nerves by the disease.

THE TREATMENT OF PHTHISICAL NIGHT-SWEATS.

By C. M. CAULDWELL, M.D.,

VISITING PHYSICIAN TO ST. JOSEPH'S HOSPITAL; INSTRUCTOR AT THE NEW YORK POLYCLINIC.

In the hope of obtaining a remedy which would permanently control the exhausting night-sweats of phthisis, I have made a series of experiments with several recognized remedies. These experiments have extended through a period of two years, with the results given below.

The ideal sought for was a drug which would not only accomplish the desired end, but which would do so *without* producing unpleasant symptoms, or in any way depressing the general condition of the patient.

Appropriate cases for experimental purposes were selected from five hundred patients suffering from chronic thoracic disease, in my charge at St. Joseph's Hospital, the New York Polyclinic, and the Northwestern Dispensary.

Care was taken to keep the patients upon the same general treatment during the trial of the various anti-sweating remedies.

This consisted of cod-liver oil, hypophosphites of lime and sodium, cinchonidine, and iron when not contra-indicated.

Atropine, ergotin, salicin, digitalis, aconite, oxide of zinc, paracoto bark, and picrotoxin were among the more important drugs selected for trial.

Each drug was tested in from fifteen to twenty-five cases.

Atropine, when given in sufficient quantity to check the perspirations, frequently produced annoying throat dryness, insomnia, anorexia, or diarrhoea. Moreover, in the majority of cases where it agreed, the sweating would reappear as soon as the drug was discontinued. The amount prescribed in twenty-four hours varied from one sixtieth to one twentieth of a grain.

Ergotin, which was strongly recommended by Professor Da Costa in a very interesting lecture, published in the "Medical News" for August, 1881, failed completely in my hands. It made considerable impression on the sweating, but, in almost every instance, produced either nausea, colicky abdominal pain, or some other form of gastro-intestinal disturbance. It was administered in gelatin-coated pills, from three to eight grains, in divided doses, being given in twenty-four hours.

Digitalis, even in large doses, although of great value in other respects, gave neither prompt nor encouraging results so far as the perspirations were concerned. The solid extract was the preparation used. From three to six grains were taken in twenty-four hours.

Aconite, recommended by homœopathic writers, greatly modified the sweats. It did this without producing unpleasant symptoms, but, as a rule, it gradually lost its power, and the troublesome symptom returned. One eighth of a drop of the tincture was given every hour or two, from ten o'clock in the morning till ten in the evening.

Paracoto bark, so highly praised by several English physicians, acted with remarkable promptness in a number of cases. In others it gave little or no relief. It had a tendency to constipate. When diarrhoea and sweating were associated, it was most satisfactory. The preparation employed was a fluid extract prepared by Parke, Davis & Co. From twenty to forty drops were given three times daily.

Salicin proved eminently unreliable, and apparently increased the debility of many patients when continued for more than a week. From one to two drachms were given in twenty-four hours.

Oxide of zinc, though increased to half-drachm doses, manifested but feeble and uncertain controlling power.

Picrotoxin, recommended by Dr. Ringer and Dr. Murrel, more nearly approached the ideal in view than any of the other drugs. It was prescribed for twenty consumptives suffering from profuse night-sweats. In seventeen of the

cases the perspirations were entirely checked, or so far diminished as to produce no further debility or annoyance. Even when given in much larger doses than are ordinarily prescribed, it caused no disturbance of the nervous system or of the gastro-intestinal tract—in fact, produced no evil effect whatever. In this respect it compared very favorably with atropine, ergotin, etc. A single full dose of the drug at bed-time was generally sufficient to control the sweating for twenty-four hours.

Where one dose failed, a second was taken shortly after midnight.

The initial dose, mentioned by Ringer and the English writers generally, is the one hundred and fiftieth of a grain.

This was found much too small, and was accordingly increased to one fortieth of a grain.

The following notes of five typical cases treated with picrotoxin will best illustrate the doses used, the length of time the treatment was continued, the permanency of effects, and the class of patients chosen for experiment. It will be noticed that Cases I and V represent the consumptives whose sweating is apparently due to nervous debility, while the same symptom in Cases II and IV is merely a part of a septic fever. It is curious that the same remedy should influence symptoms with such different causes.

CASE I.—Laryngeal Phthisis with Slight Infiltration of Left Apex.—R. T., male, aged twenty-eight years, marble polisher. Father died of "consumption of the throat." Patient's general condition is fair, digestion good, cough dry and laryngeal, very slight rise of temperature in the evening, but each night has so profuse a sweat that bed-clothing, mattress, and pillows are thoroughly soaked. Quinine, ergotin, sage tea, and paracoto bark have failed to relieve. Atropine, in heroic doses, lessened the perspirations, but rendered the patient delirious and greatly aggravated the laryngeal symptoms.

February 14th and 15th.—Took one fortieth of a grain of picrotoxin. Had very profuse sweats during both nights.

16th.—Doubled the dose. No sweating.

17th.—Same dose. Moderate sweats toward morning.

25th.—Since last note has continued the same amount. Sweats have almost ceased. Dose to be gradually diminished.

March 1st.—Sweating entirely disappeared. Discontinue drug.

May 1st.—No return of perspirations since last note—a period of two months—although the patient has not gained ground during that time.

CASE II.—Large Cavity in Upper Third of Left Lung.—M. C., female, aged twenty-six years, housewife. Family history good. Patient's last child was born four months ago; since that time she has been running down rapidly. Is now very feeble, much emaciated, no appetite, severe cough, profuse expectoration, chills, high fever, and each night an exhausting general sweat. Quinine, atropine, and aconite have been "tried and found wanting."

January 1st.—Take picrotoxin (gr. $\frac{1}{40}$ at bed-time) for one week.

8th.—Has perspired almost every night, but much less profusely. Continue treatment.

15th.—Sweats have nearly ceased and now give no trouble. Gradually diminish the dose.

April 5d.—No sweating during the past two months. Patient improved beyond expectation. Lung symptoms all subsided. Physical signs of dry cavity remain.

CASE III.—*Extensive Infiltration of Both Upper Lobes.*—R. Q., female, aged twenty-six years, seamstress. Mother and a sister died of "quick consumption." For five months the patient has not menstruated, and has failed steadily, with phthisical symptoms. Now greatly emaciated, bed-ridden, has occasional diarrhœa, severe cough, profuse expectoration, and, during sleep, a perspiration sufficient to saturate her clothing, pillow, sheets, etc. Full doses of atropine control this symptom, but aggravate the cough and produce diarrhœa. Quinine does not relieve. Ergotin checks the sweats, but causes vomiting and colic.

December 27th.—Give picrotoxin (gr. $\frac{1}{16}$) at bed-time for a week.

January 6th.—Sweating considerably diminished. Continue treatment.

16th.—Though the girl is slowly sinking, the sweating has practically ceased. Suspend treatment.

March 15th.—No return of sweating for the past two months, although she has grown steadily worse, and is now about to change worlds.

CASE IV.—*Large Cavity in Upper Lobe of Right Lung.*—G. W., male, aged twenty-nine years, shoemaker. Family history of phthisis. Patient has been "going into a decline" for over a year. At present much emaciated, just able to get about his room, temperature high, irregular chills, constant cough with profuse expectoration, and copious "sleep sweats" followed by great prostration. Cinchonidine, zinc, salicin, and digitalis have failed. Atropine in sufficient doses to check this symptom produced delirium.

December 20th.—Ordered picrotoxin in one-eightieth grain doses three times a day for a week.

26th.—Sweating has been more profuse than ever before. Give one twentieth of a grain at bed-time for a week.

January 3d.—Sweating rapidly diminishing. Continue treatment.

9th.—No sweating. General condition much improved. Stop treatment.

March 24th.—No return of sweats for past six weeks. General improvement continues.

CASE V.—*Consolidation of Upper Third of Right Lung.*—J. S., male, aged twenty-six years, brewer. No family history of phthisis. Has had well-marked lung symptoms for six months. General condition fair, cough slight and dry, appetite and digestion good, temperature never reaches 101° F., but there is a drenching "sleep sweat" each night. Belladonna and sulphuric acid do not check this symptom.

November 1st.—Take picrotoxin each night for a week. Dose, one twentieth of a grain.

9th.—Sweating has diminished to slight moisture about the forehead and breast. Continue with one eightieth of a grain doses.

15th.—Sweating has ceased entirely. Stop picrotoxin.

January 25th.—During the past two months there has been no return of this symptom. General condition markedly improved.

71 WEST FIFTY-FIFTH STREET.

Changes in the German Faculties are announced as follows by the "Progrès médical": Dr. Wolff has been nominated an extraordinary professor at Berlin, and Dr. Hack at Freiburg; Dr. Frankel and Dr. Litten have been nominated ordinary professors at Berlin; Professor Grützer has been called to Tübingen, to take the place of Professor Vierordt; Dr. Mendel, a *Privat-Dozent* at Berlin, has been nominated extraordinary professor of psychiatry, and Dr. Tuzcek, of Marburg, has been made *Privat-Dozent* in the same branch; Professor Braun, of Heidelberg, has been called to the chair of clinical surgery at Jena.

LOSS OF AN EYE BY TRAUMATISM; A PHENOMENAL SYMPTOM.

By DAVID WEBSTER, M. D.,

PROFESSOR OF OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC.

MR. G. L. C., a die-cutter, aged twenty-one, came under my observation on December 19, 1874. He stated that in the month of August, about four months previously, while cutting a die, the chisel broke, and one or more pieces of steel flew up and struck his right eyeball. The injury did not cause severe pain at the time, nor did it even temporarily destroy the sight, as he found that on closing his left eye he could see his hand with the injured one immediately after the blow. He placed himself under the care of a competent physician, and in ten days most of the pain and inflammatory symptoms had passed off, and a considerable amount of vision was restored.

Upon testing his vision I found

R. V. = $\frac{15}{100}$; no improvement with glasses.

L. V. = $\frac{20}{20}$, $\frac{20}{20}$ with — c. axis 10°.

The iris of the injured eye was discolored, and the pupil was dilated by atropine, which he had used daily since the injury.

Ophthalmoscopic examination showed whitish floating bodies all through the vitreous, probably the results of hæmorrhage with consecutive fatty degeneration. The left eye was ophthalmoscopically normal.

He was advised to stop treatment and resume work.

I examined him again on September 2, 1875, a little over a year after the injury, and found the conditions essentially the same.

He came to see me a third time on April 13, 1882, when I found that he had developed a cataract with total synechia posterior of the injured eye. The vision was reduced to perception of light, and that only in limited portions of the visual field. The vision of his left eye remained normal, but he had begun to be troubled by a "kind of floating shadow" before it. The injured eye was abnormally soft to the touch, and he said that it had been, at times, painful and bloodshot.

In a letter from the patient, dated March 19, 1883, after informing me that for some time back blood had, at times, appeared in the anterior chamber of the injured eye, but had disappeared on his quitting work, he went on to say:

About two weeks back it came on again. The blood would seem to come out at the lower edge of the iris, and, as I bent my head over my work, would almost cover it. I did not stop work this time, and it has not gone off. You will see by your book I said I could see something floating in my other eye. I think this has changed in some way. It gets in my way now as I work, and makes a blur in one little place. I can see as distinctly as ever, except when I bend my head over, and then I have to keep my eye moving if I wish to look very close.

I wrote to him advising enucleation, and on August 7, 1883, when he came to the city to have the operation performed, I made the following note:

The eyes remain generally about the same as at last visit, but are worse at times. The hæmorrhages into the anterior chamber of the injured eye have occurred at periods varying from one month to two or three months, and, when these come on, the other eye seems to sympathize, especially if he continues

working. He came into the office with his anterior chamber perfectly clear, and by leaning forward for a few minutes brought fresh blood into it which ran along the posterior surface of the cornea nearly to its center.

L. V. = $\frac{2}{3}$; $\frac{2}{3}$ with + $\frac{1}{4}$ c. axis 90°.

The ophthalmoscope reveals nothing in the left eye to account for the "floating shadow" of which he complains. There is no redness or tenderness on pressure of either eye.

The eye was now enucleated under ether, with the assistance of my friend, Dr. O. D. Pomeroy, who also witnessed the voluntary bringing of blood into the anterior chamber. It was placed in Müller's fluid.

The eye was examined by Dr. T. Mitchell Prudden, Pathologist to the Manhattan Eye and Ear Hospital, who reported as follows:

November 21, 1883.—The examination of the eye of G. L. C. results as follows: The cornea appears in all the parts examined to be normal. The anterior chamber contains a homogeneous coagulate, doubtless caused by the preservative fluid. In the extreme periphery of the anterior chamber are a few scattered red blood-cells. The iris is normal, except that a considerable number of pus cells are in places closely clustered along the walls of the smaller vessels. The posterior chamber contains numerous blood-cells. The anterior capsule of the lens, slightly separated from its body, is closely adherent to the edges of the pupillary opening. The substance of the lens, particularly in its anterior portion, is degenerated—larger and smaller ovoidal and irregular cavities filled with shining lumps of lens detritus. The laminae of the suspensory ligament of the lens are widely separated by an accumulation of fluid which contains a moderate number of red blood-cells, a small amount of free degenerated hemoglobin, and some granules of the same inclosed in small spheroidal cells (evidence of older hæmorrhages and degeneration of the blood pigment). The ciliary body is normal except for great congestion of the larger blood-vessels. In the anterior portion of the vitreous cavity are numerous larger and smaller collections of red blood-cells, a few small spheroidal cells, and large spheroidal cells, some of which contain degenerated blood pigment. Free granules of degenerated blood pigment are also present here. The remains of the vitreous are in general softened and disintegrated. Retina completely detached. The extra-retinal space is filled with fluid which contains red blood-cells and free granules of blood pigment. The detached retina shows in places the commencement of proliferative change and localized areas of œdema. Its outer layers are completely degenerated and the fibers of the same mingled with red blood-cells. The larger retinal blood-vessels are in places exceedingly congested. The choroid is somewhat compressed and its vessels are nearly empty of blood.

The examination did not reveal the exact seat of injury, nor, as was to be expected, was it possible to determine the exact seat or seats of the hæmorrhage.

Anatomical Diagnosis.—Injury to eye, hæmorrhage into all the cavities, recent as well as old, posterior synechia, commencing degeneration of the lens, complete detachment of the retina with proliferative œdema and degeneration of the same.

I saw Mr. C. three or four months after his eye was enucleated. The tissues of the orbit were shrunken so that his artificial eye had a sunken appearance. He was also obliged to remove it frequently in order to cleanse it and the cavity of a slimy mucous secretion which bathing with

astringents had failed to arrest. He still complained of the "floating shadow" before the left eye.

The prompt appearance of blood in the anterior chamber of the injured eye, upon inclining the head forward, was a phenomenon that I had never observed before, and I was at a loss to account for it. In the light of Dr. Prudden's examination, however, the mystery disappears. He found more or less old and recent hæmorrhages in all the cavities of the eye, and great congestion of the larger blood-vessels of the ciliary body. Probably the walls of the ciliary and other blood-vessels of the interior of the eye had become so weakened or brittle from long-continued inflammatory processes that the extra amount of blood forced into them by the dependent position of the head was sufficient to rupture them and allow the escape of their contents.

DIPHTHERIA SPREAD BY ADULTS.*

By A. JACOBI, M. D.,

CLINICAL PROFESSOR OF DISEASES OF CHILDREN IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

To elucidate some mooted points connected with the ætiology of diphtheria, I shall mention, among the cases of infectious diseases in the children's service of Bellevue Hospital, two of diphtheria. They could not remain in the ward any longer than was required for their removal to the fever hospital, but a sufficient time was given to study the cause of the disease. The cases were those of a girl of six, and one of three years of age. Both were inmates of the hospital in the winter of 1882-'83.

The first was admitted because of bronchitis. Foul odor from the mouth and glandular swelling round the neck directed the attention to the throat, which was filled with diphtheritic membranes. Four days previously the child was quite well; there were no other children in the room in which she had lived with her mother. The latter was a working woman, stout and robust. For weeks she had felt her throat sore, endured quietly some pain in swallowing, and went about her work. When her throat was inspected, weeks after, there was some loss of substance, some hyperæmia, but no longer any membrane. That there had been I did not doubt, nor do I to-day. It could not be ascertained that there were any children sick with the same affection in the house, and the inference must be that the little girl caught her severe diphtheria from her mother, who was not so sick with the same affection as to be prevented from working.

The second patient was brought in without a diagnosis. Within two days measles broke out. Her removal was ordered, but not completed before a small membrane made its appearance on one of the inflamed tonsils. In this case it was reported that a woman living on the same floor had a sore throat; of what description could not be ascertained.

In connection with these cases I venture to lay before you the following facts and considerations:

No permanent spontaneous generation is claimed, or has been proved, for cholera, scarlatina, or variola. Nobody looks for their primary cause in moist walls of houses, dry dust of streets, in the prevalence of previous house epidemics of typhoid fever, measles, or other eruptive diseases; in bad

* Part of a paper read before the Medical Society of the County of New York, September 22, 1884.

ventilation; in the odors of hospital wards; in putrefying kitchen refuse, or in the exhalation of sewers. But both medical men and laymen are found to be inexhaustible in accusing and condemning all those detrimental influences, not as being predisposing elements, not because of their injurious influence on health in general and on the condition of mucous membranes in particular, but as the main and frequently sole causes of diphtheria. In the minds of many physicians, diphtheria is intimately linked with sewerage; with them the trap of the water-closet and the plumbing of the cellar are the first objects of attention; the patients' and their families' fauces and nares coming in for a relatively smaller part of their care. If they would pay more attention to the direct sources of contagion, which is something understood and definite, than to the indefinite and unproved presumption of specific poisons in the outlets of the house, or the inlets from the sewers, their aetiology would be something more positive in a great many cases.

I do not mean to say that the house hygiene ought not to be looked after by the physician in every case of sickness, but the more I have seen the more it has occurred to me that we may live to reach the conviction that there is but one predisposing element, viz., a sore mucous membrane, and but one cause of an individual attack of diphtheria, viz., direct contagion.

Letting alone diphtheria of wounds and of cavities, the disease affects the oral and pharyngeal spaces, and the respiratory organs. It is the territory invaded on which the danger to the individual is dependent. The size of the membrane and its seat determine the character of the disease, *cæteris paribus*. While a tonsillar diphtheria is attended with scarcely any danger, a laryngeal diphtheria destroys a child by strangulation, and nasal diphtheria by sepsis. The character of the epithelium, whether pavement or cylindrical, the presence or absence, copiousness or scarcity of muciparous glands and lymph-ducts, decide the nature of a case. All this is well known. In my treatise on the subject* I have tried to settle these questions permanently.

It is just as well known, however, that the definition of the term of diphtheria, as it does not depend upon the size or seat of the membrane, is also not limited by the character of the symptoms. A high or a low temperature, muscular or pharyngeal pain, difficulty in deglutition or articulation, sepsis, glandular swelling, may be present or absent in a case of diphtheria as long as the characteristic membrane is met with. It is always diphtheria, dangerous to a certain degree to the individual by its direct effect; to a much larger extent, however, to uncounted others by its potential influence, its contagiousness. No matter how slight a case may be at a given time, it can extend to the nares or the larynx; or terminate in paralysis or death. Besides all that, it is communicable to another person; a mild case may as well generate many severe ones, as a severe one need not necessarily be the source of misfortune to others. For neither in diphtheria nor in other contagious diseases is contagiousness the unavoidable *sine qua non*. Neither variola, nor scarlatina, nor even measles, strikes every person within

striking distance. While a cannon-ball, however, may miss, a pistol-bullet may carry destruction.

Such a bullet is many a case of the so-called follicular amygdalitis (tonsillitis). There is such an affection as deserves the name. It implies a catarrhal or suppurative condition of a tonsillar crypt, or several of them. It may be obstinate and extend over years, giving rise to constant returns of the secretion, or to concretions. In the acute stage, even in the chronic, it will permit of the introduction of a probe into the duct to a depth of from one to two centimetres. The color of the secretion is often that of a membrane, not its nature, nor consistence, nor location (still it may become diphtheritic even inside the duct), and in that condition it is not diphtheria. But the large majority of cases which are commonly called follicular tonsillitis do not belong to this annoying but innocent class; most of them are diphtheria. Not everything not fatal need be called by a different name. What to-day looks like a point, or four or five points covering the outlets of ducts, may to-morrow be a confluent membrane. Just as well, you might withhold the name of variola from a case of small-pox so long as it was not confluent or did not destroy life. You have a family sick with affections of the throat and nose; a child is dying of laryngeal croup, another of nasal diphtheria, glandular swelling, and sepsis; others have severe pharyngeal affections; others but slight tonsillar tufts, which may or may not coalesce and extend into membrane. Is the first one "croup," are the others "diphtheria," is the last one "follicular amygdalitis"? Or the first case in a family was just such a one as was denominated tonsillar folliculitis by the family physician, and no preventive measures were taken to protect the rest of the little flock. From that moment it was that extermination began in that family. We have all seen it; we ought to heed it all.

Diphtheria in the adult is not so rare as it is reported to be. It is true, extreme cases are rare. Diphtheritic strangulation is not frequent; still, of about four hundred and fifty tracheotomies, I have performed two on adults—one on a man of fifty-five with an ossified trachea, and one on a lady of thirty-two. Diphtheritic sepsis is not very frequent either in the adult, the action of the lymph system being the more pronounced the younger the individual.

In this respect, sad experience had taught the boards of the French hospitals for sick children the frequency of diphtheria in the adult officers and employees of their institutions. A report, rendered by a special commission appointed for the purpose of inquiring into the possibility of preventing the contagion of diphtheria in those adults, is printed in the "Union méd." of December 3, 1881. It recommends protracted carbolic spray in the wards (!) and dead-houses, an increase in the number of nurses, of washing and bathing establishments, and an improvement in the housing, boarding, and pay of the medical officers.

Mild affections in adults, punctate deposits terminating in membranes on the tonsils, membranous streaks extending, vertically in most cases, over the posterior aspect of the tonsils, are frequent. It is not necessary that from their children alone father or mother who attended them should be infected. In many cases the source of the affection can

* "Treatise on Diphtheria," New York, William Wood & Co., 1880.

not be traced at all. The symptoms are often but few. A little muscular pain and difficult deglutition are, perhaps, all that is complained of. Women will quietly bear it; men will go about their business. An unmarried shopkeeper called on me several times in the course of a few weeks for a trifling complaint. Of his throat he did not speak at all; but I discovered a few patches, first on the left, store on the right, tonsil. My warning not to go to his store, lest he might get seriously ill or infect others, was not heeded. He attended to his business, coming in contact with a hundred women and children daily for weeks, until he was laid up for a week, to return to his dangerous and nefarious occupation as soon as he felt a little better. A school-mistress I have known to teach all day, for ten days, with diphtheritic patches in her throat. I could prevail upon her to retire a week from work only by threatening that I would communicate with the parents of some of her pupils about the danger the children were running. Two families of my acquaintance had the same experience, with their large houses full of children. They had never had diphtheria until they employed a seamstress, who came daily from her residence in another part of the city. Attacks of diphtheria followed each other in quick succession. The houses were examined from attic to cellar, the sewer was disturbed, the traps were changed. The health of the people did not change with the plumbing. At last the suspicion of contagion was roused. The seamstress came from a neighborhood and a family where diphtheria was endemic. From that time the woman was dispensed with, and no diphtheria has made its appearance in those families these six, and three, years. In the family of a physician there were two children—a boy, in good health otherwise; a girl, robust and vigorous. Both suffered from diphtheria repeatedly for many years, until the girl came near dying, and the boy died. What was the cause of the constant attacks dragging over years? The fact had been overlooked that it so happened that almost every time when the children were sick the old, trusted, and trustworthy nurse was also affected with diphtheria, sometimes seriously. What, however, was not known at that time, and was discovered later, indeed too late, was that the woman had concealed many an attack of throat disease, fever, difficult deglutition, out of a sense of duty; that she had often repeated those medicines which she had been supplied with before. In the early part of the summer of 1883 the boy died; the surviving girl was sent to the country; also the nurse, who had been sick with diphtheria for weeks. While in the country the child was not in so close and intimate company with her nurse as in the city and in winter. They returned to the city in September. In October the child was taken sick with diphtheria, the nurse having taken "throat medicine," unknown to anybody, for some time. Then the nurse was discharged; that was the end of the boy, and of diphtheria in that family.

If I add that in several families diphtheria broke out among the children after new servants had been engaged, and that these servants were found affected with throat disease, I think I only state the experience of many other practitioners.

The danger arising from the contagion spread by adults

affected with mild forms of diphtheria is increased by the fact that in them diphtheria is apt to assume a chronic character without losing its contagious nature.

In the third volume of his "*Traité clinique des maladies de l'enfance*," Paris, 1884), Cadet de Gassicourt quotes (p. 299) Salomon, who, more than eighty years ago, asserted that croup was a chronic affection, now and then; also Vieusseux, who, in 1812, alluded to four cases of prolonged croup. A protracted case of diphtheria is also mentioned by Empis ("*Arch. gén.*," 1850), and Hybre (1875) and Garcia Rijo (1878) made the same subject the theme of their Inaugural Theses.

In my "Treatise on Diphtheria" I have reported a case in which epiglottic and laryngeal diphtheria lasted a month, and terminated in recovery. Inspection proved the disappearance of old, and the formation of new, membranes during that time. Sanné has the observations of croup patients who recovered after a duration of 27, 32, and 60 days. Cadet de Gassicourt had to perform tracheotomy in cases of croup after they had lasted 18, 23, and 43 days. The first patient recovered; the two latter died. Barthéz emphasizes the long duration of membranes; they may last a month before being exfoliated and expelled. When they are exfoliated and expelled, they may form again in a few hours. A case in which the tracheal membrane below and above the bifurcation was formed anew in seven hours, I have reported in my treatise. Another case is as follows: At three o'clock p. m., on June 6, 1883, I observed in the throat of a girl of four years thick, pulpy membranes on the tonsils and pharynx; in the mouth absolutely nothing. They had been there a day and a half. At half past five I saw the child again. The cheeks, the tongue, the inner aspects of both lips, were covered with a dense, uniform pseudo-membrane.

Isambert has the case of a medical assistant who for fully nine months (both in Paris and abroad), and even after his general health had been considerably improved, expelled membranes daily from his nasal cavities. Cadet de Gassicourt publishes cases of pharyngeal and nasal diphtheria of 45 and 151 days', and one of laryngeal diphtheria of 65 days' duration. Most of the cases recorded ended in recovery.* While the disease lasted it was a source of danger to the person affected. This, however, is *not the greatest danger*; the contagion spreading from them is of greater importance than the risk run by the individual. Nor is the severity of such a case the most formidable danger. For a person dangerously ill is in bed, and a source of evil to those only immediately around him. Those, however, who feel well, or well enough to be about, are the scourge of the community at large, particularly as mild cases, being neglected, have a tendency to last long.

Isambert's assistant was traveling half a year to get rid of his nasal diphtheria. He recovered; but how many deaths did he spread, from railroad-car to railroad-car, from stage-coach to stage-coach, from hotel to hotel? To all these curses strewn out by the luckless wanderer after his own health, how many physicians have looked, in the sporadic cases occurring here and there, and in the epidemics

* "*Revue mens.*," 1884.

or epidemics generated by them, for the local cause of the supposed primary indigenous origin? Nobody suspected the traveler, who probably left days before, as nobody traces every outbreak of cholera to the unknown person who carried it upon his person or in his bowels.

These and other cases have induced me, while not overlooking the hygienic condition of the house, to look after the source of a diphtheritic attack in the persons of the friends and attendants. A family with children ought to insist upon the occasional inspection of the throats of their help; servants with chronic pharyngeal catarrh must not be hired. A seamstress, coming for an occasional day's work, ought to have her throat inspected; cooks and nurses must be looked after, the more carefully, the less such people are inclined to give way to their pains or ailments, or throw up their places. A sick nurse introduced into a family must be examined; she will go from one place to another, and carry pharyngeal and puerperal diphtheria. It is true that I know of no case, at least I can prove none, in which a physician carried the disease without having it himself. I know of many, though, who contracted it, although their visits in a patient's bedroom are but brief, and they are not very much exposed, except in cases of tracheotomy, etc. Many dozens of cases, however, are known to me in which the nurses were taken sick.

Thus, if there be any class of persons who are the constant transmitters of diphtheria, and require attention and caution, it is nurses and cooks—in fact, all domestic help; also sick-nurses, teachers, hair-dressers and barbers, shop-keepers, restaurant-keepers, and all those people who are in constant contact with all classes and ages. The physician enjoys a certain degree of both active and passive immunity, but it depends on the number and duration of his exposures whether he becomes more or less both endangered and dangerous.

What I have said may be very trite and trivial. But it so happens that I have seen a good deal of diphtheria these twenty-five years, and have tried to study and know it. I have, like others, studied the ætiology of the disease, and looked after the source of every individual case; have examined numberless traps and sewers; accused all sorts of causes, and have been impressed, like most others, with the idea that diphtheria might, after all, prove indigenous in houses and districts from local causes. The only thing I have not done in this direction is to discover a third or fourth variety of bacterium, and to proclaim it as the sole and infallible source of the evil. But the more I found that the sewerage, and cold, and other influences were but the suggestions of presumption and fear, and that I could not find a clew to a single case in external circumstances and influences, the more did I look for direct contagion in each case. It has taken me a long time to become convinced that it will be better, both theoretically and practically, to take nothing for granted, and to look for such facts as I can prove. As I said before, neither for variola nor scarlatina do we look in moist walls or sewers, but trace a case back to whosoever may have communicated it. It has dawned upon me too late that it is just so with diphtheria, and that preventive measures will be more effective

when we look for the cause of every case of diphtheria in the nares or throats of living persons. *There is as much diphtheria out of bed as in bed; nearly as much out of doors as indoors.* Many a mild case is walking the streets for weeks without caring or thinking that some of his victims have been wept over before he was quite well himself.

If I were to condense what I have had the honor to read, these would be the main points:

There is probably no spontaneous origin of diphtheria any more than there is a spontaneous origin of cholera or scarlatina.

Diphtheria is contagious. Severe forms may beget severe or mild forms. Mild cases may beget mild or severe cases.

What has been called follicular tonsillitis is *mostly* diphtheria. It is seldom dangerous to the patient, as the tonsils have but very little lymph communication with the rest of the body. But it is contagious.

This form is frequent in the adult, in whom it loses nothing, however, of its contagiousness.

Diphtheria in the adult proves dangerous to the community mostly because it does not restrain the patient from communicating the disease.

It is apt to last long: Firstly, because most cases occur on a surface covered with pavement epithelium (tonsils); secondly, because of the constant exposure and neglect on the part of the patient. Even without it, diphtheria may last weeks and more; with it, it is subject to sudden relapses. As long as it lasts it is contagious.

As diphtheria is but a mild affection in many adults, who disregard it and frequently do not care to mention its existence, pain in swallowing and moderate malaise being the only symptoms, the question of transmission by means of clothing, etc., on the part of third persons is capable of becoming more difficult to answer than it ever was. Many a case which has been believed to be thus carried is probably one of direct contagion from a patient to a second person, from this second to a third.

Clinical Reports.

ROOSEVELT HOSPITAL.

CLINICAL REMARKS BY HENRY B. SANDS, M. D.

Traumatic Stricture of the Urethra; External Urethrotomy.

GENTLEMEN: I will show you to-day a case of stricture of the urethra. The patient first came under my observation two or three days ago. He is a Scotchman, forty-three years old, and gives the following history: He suffered from gonorrhœa twenty-five years ago, the discharge lasting for several months. He was treated by injections, and recovered completely. In 1875, while at sea, he was carried by a wave across the deck and struck his perineum against a beam. He suffered afterward from severe pain at the seat of injury, had bleeding from the penis, and was confined to bed for three weeks. Micturition was painful, but he escaped retention of urine, and recovered without surgical treatment. Since that time he has had occasionally pain in the perineum, and hæmaturia. About a year

ago he had an attack of retention of urine which lasted for several hours, and then passed off without the use of instruments. During the attack he bled copiously from the penis. About the middle of December last he began to pass his urine nearly every hour of the day and night. The stream became small and twisted and flowed slowly, with pain in the perinaeum. In January his symptoms increased in severity, and since the end of January he has gradually lost flesh and strength. He also suffers from pain in the back and head, has photophobia and occasional nausea, is restless at night, and is obliged to pass his urine very frequently, micturition being painful. The urine is pale and of low specific gravity (1.007), it has an acid reaction, and contains ten per cent. of albumin and a moderate amount of pus. Dr. Hobbie, who has had the care of the patient, informed me that he had made a careful examination of the urine several times, and had failed to discover any microscopical evidence of renal disease. Since the patient entered the hospital the urine has been again examined microscopically, with a negative result; but the amount of albumin present in the urine and its low specific gravity suggest that there may be renal disease in addition to the disease of the urethra and bladder. It is with some misgiving, therefore, that I undertake the operation I am about to perform; for, as you are aware, when renal complications exist, operations on the urethra or bladder are attended with serious risk. Nevertheless, as the patient's life is rendered miserable by his infirmity, and evidently can not last long unless relief is afforded, the existence of renal disease is a matter which affects prognosis rather than treatment, for the operation is not inevitably fatal, and it offers the only possible means of cure.

The stricture is situated in the bulbous part of the urethra, and is quite close, no instrument having yet been made to pass it. I hope to be able now, however, to pass through the stricture a filiform elastic or whalebone bougie, and to use this as a guide in performing external urethrotomy. The stricture is traumatic in character, and would not be amenable to treatment by dilatation. Having now completed the operation, it may be profitable to you if I direct your attention to a few points connected with it, which ought to be kept in mind in case you should be called on to perform it. Notice, then, in the first place, that, after several trials, I succeeded in introducing through the stricture a filiform whalebone bougie, which served as a guide at a later stage of the operation. A metal guide would have been preferable, had I been able to pass it but even this thread-like piece of whalebone proved of the greatest advantage by enabling me to use the knife with precision in dividing the stricture. In performing the operation of perineal section without a guide, the surgeon is often puzzled while searching for the orifice of the stricture, and occasionally fails to discover it, in which case he is compelled to unite the proximal with the distal parts of the urethra by cutting through the intervening callous tissue, without following the exact course of the canal. But, if the latter can be traced and the urethra laid open at the seat of stricture, a good result is much more likely to be obtained; hence the advantage afforded by a guide, however small, in facilitating this delicate and important step of the operation.

In the second place, you may have observed that, when the urethra had been freely laid open by cutting on a grooved staff, the point of which was held immediately in front of the stricture, a loop of silk thread was passed through either edge of the urethral incision, so that the deeper parts could be drawn asunder, thereby bringing into view the orifice of the stricture and permitting the easy introduction of a slender grooved director, along which a narrow-bladed knife was made to divide the indurated tissues sufficiently to overcome all resistance. Unless

the deep parts are held aside by some method like that I have described, it is impossible to explore and divide the stricture with the requisite delicacy and precision.

Finally, you saw that the constricting tissues were completely divided, so as to allow the introduction of a full-sized sound into the bladder. When the knife is thus freely used, a recontraction is less apt to occur than when the stricture has been only partially divided. In certain cases, however, in which the induration is extensive, a radical cure can not be hoped for, and the occasional employment of a sound will be required to prevent a recurrence of the disease.

[The patient continued to lose strength after the operation, and died of exhaustion on the tenth day. Post-mortem examination showed dilatation of both ureters, and dilatation and degeneration of the right kidney.]

Book Notices.

Clinical Chemistry. An Account of the Analysis of the Blood, Urine, Morbid Products, etc., with an Explanation of some of the Chemical Changes that occur in the Body in Disease. By CHARLES HENRY RALFE, M. A., M. D., F. R. C. P. L., Assistant Physician at the London Hospital, etc. Illustrated with 16 Engravings. Philadelphia: Henry C. Lea's Son & Co. Pp. ix-308.

This little book aims to give in brief compass the chemical composition and reactions of the animal tissues and fluids both in the normal and in the morbid state. But, as its title indicates, it regards rather the clinical than the physiological aspect of its subject; and, accordingly, it differs from a book like Gamgee's "Physiological Chemistry" in containing only so much chemical matter as will be of assistance to the physician in the diagnosis of disease. In accordance with this plan, the general introduction, in which are enumerated the chemical principles entering into the animal constitution, is condensed to the utmost degree. Much more elaborate is the account which follows of the analysis and tests of the different fluids of the body—blood, chyle, lymph, and milk. To the examination of the urine seventy pages, or nearly a quarter of the work, are devoted; and these contain nearly everything that the physician requires for clinical purposes. In this connection Ralfe gives some (although not all) of the more recent tests for albumin and glucose in the urine—tests which have hitherto been described only in medical periodicals or society transactions. Next in order to the urine is a description of the chemistry of the saliva and other digestive juices, and of bile, vomit, flatus, and feces; and, in connection with derangements of the liver, the author considers not only jaundice, but also diabetes and lithæmia (uricæmia). A sort of appendix to this chapter describes the processes for the examination of the stomach in cases of suspected poisoning, and for the determination of the total amount of nitrogen taken in and discharged by the organism. A chapter on the chemistry of morbid products closes the book. In this the author treats successively of calculi of various sorts; of the products of tissue degeneration; of morbid exudations, such as pus, dropsical fluids, etc.; of chemical changes in osseous lesions; and of the chemical basis of scurvy, rheumatism, and gout.

Such is the scheme which has been followed out with very fair success. The author has succeeded in compressing into about three hundred small-sized pages much that is valuable and important for a physician to know; and those who desire

a work of this scope, the perusal of which will take but little time, can hardly go wrong in purchasing his book.

There are several good illustrations, and the binding and typography of the book are tasteful.

Fat and Blood: an Essay on the Treatment of Certain Forms of Neurasthenia and Hysteria. By S. WEIR MITCHELL, M.D., etc. Third edition, revised, with additions. Philadelphia: J. B. Lippincott & Co., 1884. Pp. 164. [Price, \$1.50.]

As is well known to the majority of the profession, Dr. Mitchell is the advocate of a system of treatment the essential features of which are seclusion, rest, electricity, massage, and a dietary that may be modified to suit the pathological exigencies liable to occur in individual cases.

It is not, however, to be supposed that Dr. Mitchell imagines himself entitled to priority in the use of any single one of these factors in the treatment of certain varieties of nutritive derangement. But, while these various expedients had often been recommended separately, they had never been proposed collectively. This fact has, we conceive, been lost sight of by those who have sought to disparage the views of the author, on the score of lack of originality.

If succinctness, the practical adaptation of broad physiological laws, and lucidity of diction are praiseworthy, to this little book must be awarded the highest excellence.

The author has carefully rewritten much of it, and in its present shape it constitutes a most attractive little volume.

The Causation of Sleep. By JAMES CAPPIE, M.D. Second edition, rewritten. Edinburgh: James Thin, 1882. Pp. xv-207.

We have carefully read every page of this admirable little treatise, and we must say not only that the philosophy of the subject is well handled, but that the style also is worthy of the highest commendation. In a word, the diction is of that rare variety which conveys ideas of a weighty and even intricate character without fatiguing the mind of the reader. This in itself is a great merit, constituting as it does a quality for which every book-buyer can not but be thankful. Dr. Cappie's views of sleep are not of an extreme or one-sided character. Thus, he does not perceive in the retrocession of the encephalic blood stream during unconsciousness the sole cause of sleep, but only one of the factors of this intricate phenomenon. According to him, the anæmia of the brain during sleep is to be regarded as the consequence of the state of exhaustion engendered in the cells by previous functional activity. While in this state of exhaustion the cells have a diminished affinity for the oxygen of arterial blood.

It is impossible to do justice to the entire argument of the question in the limited space at our disposal, and we must refer the reader to the book itself, wherein will be found much both to instruct and to entertain. Dr. Cappie's little book is certainly a welcome addition to the literature of cerebral physiology.

BOOKS AND PAMPHLETS RECEIVED.

Atlas of Female Pelvic Anatomy. By D. BERRY HART, M.D., F.R.C.P.E., Lecturer on Midwifery, School of Medicine, Edinburgh, etc. With a Preface by Alexander A. J. C. Skene, M.D., etc., Brooklyn. New York: D. Appleton & Co., 1884. Pp. 89-vi-iv, and Colored Plates. [Price, \$15.]

A System of Human Anatomy, including its Medical and Surgical Relations. By HARRISON ALLEN, M.D., Professor of Physiology in the University of Pennsylvania, etc. Illustrated with Three Hundred and Eighty Figures on One Hundred and

Nine Plates, etc. Section vi.—Organs of Sense, of Digestion, and Genito-urinary Organs. Philadelphia: Henry C. Lea's Son & Co., 1883. Pp. iv-585 to 811, inclusive. [Portfolio Cover.]

Henke's Atlas of Surgical Anatomy. A Series of Plates illustrating the Application of Anatomy to Medicine and Surgery. Translated and Edited by W. A. Rothacker, M.D., Pathologist to the Cincinnati Hospital, etc. Cincinnati: A. E. Wilde & Co. Pp. xx, and Plates.

A Text-Book of Practical Medicine, designed for the Use of Students and Practitioners of Medicine. By Alfred L. Loomis, M.D., LL.D., Professor of Pathology and Practical Medicine in the Medical Department of the University of the City of New York, etc. With Two Hundred and Eleven Illustrations. New York: William Wood & Co., 1884. Pp. xv-1102.

A Practical Treatise on Disease in Children. By Eustace Smith, M.D., F.R.C.P., Physician to His Majesty the King of the Belgians, etc. New York: William Wood & Co., 1884. Pp. xxiv-844.

The Ear: Its Anatomy, Physiology, and Diseases. A Practical Treatise for the use of Medical Students and Practitioners. By Charles H. Burnett, A.M., M.D., Professor of Otolaryngology in the Philadelphia Polyclinic, etc. With One Hundred and Seven Illustrations. Second Edition, Revised and Rewritten. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xxiii-20 to 585, inclusive.

Osteotomy and Osteoclasia for Deformities of the Lower Extremities. By Charles T. Poore, M.D., Surgeon to St. Mary's Free Hospital for Children, etc. New York: D. Appleton & Co., 1884. Pp. x-187. [Price, \$2.50.]

A Text-Book of Pathological Anatomy and Pathogenesis. By Ernst Ziegler, Professor of Pathological Anatomy in the University of Tübingen. Translated and Edited for English Students by Donald MacAlister, M.A., M.B., M.R.C.P., Fellow and Medical Lecturer of St. John's College, Cambridge. Part II.—Special Pathological Anatomy, Sections i-viii. New York: William Wood & Co., 1884. Pp. x-365. [Wood's Library of Standard Medical Authors.]

A Manual of Diseases of the Throat and Nose, including the Pharynx, Larynx, Trachea, Esophagus, Nose, and Naso-pharynx. By Morell Mackenzie, M.D. Lond., Consulting Physician to the Hospital for Diseases of the Throat, etc. Vol. ii.—Diseases of the Esophagus, Nose, and Naso-pharynx. New York: William Wood & Co., 1884. Pp. vi-400. [Wood's Library of Standard Medical Authors.]

Recherches cliniques et thérapeutiques sur l'épilepsie, l'hystérie et l'idiotie. Compte rendu du service des épileptiques et des enfants idiots et arriérés de Bicêtre pendant l'année 1883. Par Bourneville, médecin de Bicêtre, Bonnaire, Boutier, Leflaive, internes du service, P. Bricon et Séglas, docteurs en médecine. Volume iv avec 8 figures et deux planches. Paris: Bureaux du "Progrès médical," 1884. Pp. xxxviii-151.

Auscultation, Percussion, and Urinalysis. An Epitome of the Physical Signs of the Heart, Lung, Liver, Kidney, and Spleen in Health and Disease. Edited by C. Henri Leonard, A.M., M.D., Professor of the Medical and Surgical Diseases of Women, and Clinical Gynecology, Michigan College of Medicine, Detroit. Fully Illustrated. Detroit: The Illustrated Medical Journal Co. Pp. 166.

Visions of Fancy. A Poetical Work. By N. M. Baskett, M.D. St. Louis, 1884. Pp. 109.

A Manual of Obstetrics. By Edward L. Partridge, M.D., Professor of Obstetrics, New York Post-Graduate Medical School, etc. With Sixty Illustrations. New York: William Wood & Co., 1884. Pp. x-295.

Proceedings and Addresses at a Sanitary Convention held at Ionia, Michigan, December 13 and 14, 1883.

Proceedings, Addresses, and Discussions of the Third Semi-annual Meeting of the Kentucky State Sanitary Council, held at Bardstown, Ky., March 26 and 27, 1884, under the auspices of the State Board of Health.

Names and Addresses of Health Officers in Michigan for the Year 1884-'85. Arranged from Returns by Local Boards of Health to the State Board of Health.

Protection and Free Trade to-day, at Home and Abroad, in Field and Workshop. By Robert P. Porter. Boston: James R. Osgood & Co., 1884. [Price, 10c.]

Correspondence.

LETTER FROM CHRISTIANIA.

The Dinner given to the International Medical Congress by the Municipality of Copenhagen.—The King's Reception.—The Close of the Congress.

CHRISTIANIA, August 31, 1884.

The grand dinner given on Thursday evening by the municipality of Copenhagen to the members of the Congress was by far the most extraordinary and unique feature of the whole meeting, and, in brilliancy, magnitude, and originality, far surpassed any entertainment of the kind on record. To describe it with

any justice would require the pen of a Goethe. The building in which it was held was erected especially for the occasion. It was made of wood and glass, and located on the edge of a quay which overlooked a beautiful view of the river and harbor, and in one of the most attractive parts of the city. Each card of invitation bore the name of the recipient, the number of the table at which he was to sit, and a plan of the general arrangement of the tables.

Promptly at the time appointed long lines of carriages filled the principal avenues of approach. The "Dannebrog" was seen suspended from every flag-pole in the city, while the vessels in the harbor were, with one accord, covered with flying clouds of color. On entering the main end of the banquet hall, the guest first found himself in a large lobby, upon each side of which were long, double rows of books—each row numbered to correspond with a table, and each book also numbered. By this means a place was secured for the hat, etc., of each guest, and without the slightest delay or confusion. Passing through the lobby, the guest suddenly found himself in a magnificent, spacious, and airy hall, the ceiling and sides of which were tapestried with a dark cream-colored stuff, relieved by trimmings of buff. Upon a double row of slender columns, which ran the length of the room, were huge clusters of "Dannebrog," beautifully grouped and arranged. The Danish flag, by the way, consists, as every one knows, of a white cross upon a red field, and for purposes of decoration is exceedingly effective. Upward of forty tables, each capable of seating about thirty-five, were arranged in rows at each side of the room, excepting in the middle, where, at one side, was a large raised platform, upon which, at five tables, were stationed the hosts of the occasion and the more distinguished guests.

Behind the principal table of all, at which the Regent of the University presided, there appeared upon the wall a huge coat-of-arms of the city, done in flowers, and more than twenty feet square. Around it were grouped the flags of all the nations represented at the Congress. On the opposite side of the room was a raised desk, from which responses to toasts were delivered. Most remarkable of all was the flood of light which filled the place. On searching for its source, one saw, besides the large skylights in the roof, that one half of one side, and the whole of the other, that toward the water, were made of glass!

Fortunately, we, with our *fidus Achates*, were stationed at the second table from the center, and, having arrived early, were allowed to select the end seats.

Again, as upon the occasion of the opening of the Congress, the guests appeared in full regalia, and, as we stood watching the company assemble, the same lavish display of richly jeweled orders was observed. There were some, notably Esmarch and Volkmann, famous men indeed, whose bosoms fairly blazed, covered as they were with glittering ornaments. There were others again, no less distinguished, with whom, as with Pasteur, one decoration was enough. While, conspicuous among all for the absence of all external aristocratic insignia, stood one, well known to every reader of this letter, whose fine countenance, manly dignity, and genial grace were in themselves an all-sufficient stamp of greatness.

Promptly at the appointed time the company was seated, and, after the military band had played the stirring Danish national hymn, the dinner was formally opened by a short speech from the Regent. Then the large doors at the farther end of the hall were thrown back, and a procession of one hundred and fifty waiters, each bearing a huge porcelain tureen of steaming soup, marched solemnly down the hall, the head of the column going the whole length of the room and finally halting at the last tables. This manoeuvre, as well as the soup, was, each in its own way, excellent. Course after course was thus served,

each of its kind appetizing, delicious, and in some instances characteristic. The wines, as at all the Danish entertainments, were varied in kind, in quantity abundant, and of the very best quality. Delightful music was furnished by the band, and also by a chorus of male voices, foremost of which was a superb baritone, the singing by which of certain beautiful Danish Folks-Lieder to an accompaniment by the other voices was worthy of the highest admiration.

During the dinner the object of the huge window toward the river-side was made evident, for, one after another, a succession of beautiful steamers, decorated to the utmost with flags, and with their decks covered with people, sailed slowly by, saluting us as they passed by dipping their colors and by a great waving of handkerchiefs from those on board.

A few short speeches were made, Pasteur, Paget, Virchow, Crundeli, and Panum, together with the celebrated antiquarian, Professor Warsaa, being the orators. Thus two hours quickly passed, and at a few minutes after seven, in the early twilight of a beautiful evening, began the most wonderful part of the whole performance. The whole company was ushered out of the dining pavilion and into the open air, where, moored one after another to the quay, were five large steamers. Upon these all quickly embarked. Then began such an ovation as no man present had ever seen before—a sight which might have recalled to Copenhagen two other such occasions—the first, when it welcomed the victorious Christian IV, most famous of all the Danish kings; and, again, years later, when the city rose as one man to greet its greatest genius, Thorwaldsen, convoyed from Rome in triumph, with all his works of art about him, in a royal man-of-war.

Our course was up the same water-way for about a mile and a quarter. Everywhere, from the beginning to the end of the sail, everywhere on both sides of the river, quays, windows, roofs, wharves, bridges, and shipping swarmed with crowds of people, who cheered, shouted, and hurraed to the utmost, and who made the places in which they stood white with the waving of a sea of handkerchiefs. Everywhere was seen the Danish flag. Every vessel, from the largest ship to the smallest yacht and fishing-boat, was in holiday attire. All along the shore fireworks were displayed. The amateur boating clubs turned out in full force, and the quiet waters were filled with wherries, gigs, and barges, many of the latter six- and eight-oared, all manned by capital oarsmen, who, in their pretty boating costumes, rowed alongside our steamers, saluting each one with their oars as they passed, the coxswain of each burning beautiful colored lights as long as they remained in sight. Slowly we made our way, until the excitement grew intense, and the oldest and most distinguished cheered and saluted with the rest. Thus, at last, the Tivoli, or summer concert-garden, was reached. There is no such Tivoli as Copenhagen's in all Scandinavia, nor, probably, in all Europe. On this occasion it outdid itself. Its beautiful pavilions glowed with colored lights until they looked like splendid set pieces of fireworks. Here and there tall poplar trees were hung with Chinese lanterns to their very tops. The little lake was surrounded with semicircles of colored lights, and pyramids of the same floated like radiant swans upon its bosom. Even the very flower-beds and fern-banks were illuminated, by methods as ingenious as they were beautiful. The display of fireworks was fine. The bands played, the pantomime and the theatre were at their best.

The "Hanlons" flew on their *trapèze*, the "Rutsch-Eahn" roared, the circular boats tore around their winding way, the revolving balloons rose and fell, people great and small swarmed everywhere, and Tivoli was ablaze.

A reception was given to the members of the Congress on Friday evening, August 15th, by his Majesty Christian IX, King

of Denmark, at the Royal Palace of Mariaborg. The attendance was large, all the leading members of the Congress being present. The company was received by the whole of the Royal family then in Denmark, namely: the King and Queen, their son, the King of Greece, with his Queen, the Crown Prince and Princess, and the King of Denmark's youngest son. The grand apartments of State were thrown open for the occasion. The Royal party were exceedingly affable and easy in their reception of the guests presented to them, and conversed steadily and intelligently with all who lingered to chat with them. The impression which they made was particularly pleasant in every respect. The jewels of the Queen of Greece and of the Crown Princess are worthy of mention, the former consisting of the usual tiara, necklace, corsage, etc., the necklace being a band composed of five strings of beautiful pearls, while the other ornaments were made up of emeralds, surrounded by large diamonds.

The emeralds set in the corsage were of extraordinary size and purity. The jewels of the Crown Princess are diamonds, and said to be of great value.

At ten o'clock supper was announced, and the company was ushered into another suite of apartments, each one of which was filled with tables covered with every luxury. Conspicuous upon the tables were the royal pheasants, each decorated with his own plumage and surrounded on all sides by game in infinite variety, and by all the other toothsome and attractive dishes which Scandinavia could furnish and French skill perfect. Wandering from room to room, one at last found himself in the grand banquet-hall, a superb room with lofty roof and of ample size, decorated in white and gold, and flanked on each side by a row of beautiful columns. In a gallery at one end was stationed the Royal Military Band, while below, at the same end of the room, the Royal Family continued to receive. Everywhere were famous men, brilliant lights, splendid paintings, princely saloons, the hum of many voices, and the strains of the music. Everywhere, too, were eating and drinking, merry-making, and feasting. Of one thing there can be no question: There is, somewhere in Denmark, an inexhaustible fountain, not of water, but of champagne. It flowed steadily throughout the whole of the Congress, and reached high-water mark on the occasion of this reception.

The Congress was brought to a close on Saturday evening by a ball and *fête*, given to the members and their lady friends at the National, a beautiful theatre opposite the Tivoli. Although a number had already left the city, the attendance was large and the occasion very enjoyable. A fine supper was served, the music was capital, and dancing was continued until a late hour. Everybody waltzed, young and old, including Professor Esmarch, and thus the Eighth International Medical Congress was brought to a happy and most successful termination.

In reviewing the events of this memorable week, there are some things which should not pass unnoticed. Although by no means a large and wealthy state, such were the liberality, thoughtfulness, and ingenuity of our entertainers, that they made their Congress by far the most enjoyable one on record. Again, although, for political reasons, even such an assemblage could not be brought together without great danger of serious controversies, such were the dignity, fairness, and good temper of those in charge, that all passed off smoothly; the spirit of the meeting was, on the whole, a united one; and, finally, every one seemed to depart satisfied and happy. All honor, then, to our brave, courteous, and generous friends, the Danes; and when they come to visit us in Washington, three years from now, let us show them that we have not forgotten their genial kindness and their splendid hospitality.

D. APPLETON & Co.

Edited by
FRANK P. FORSTER, M. D.

NEW YORK, SATURDAY, SEPTEMBER 27, 1884.

THE HOSPITAL SUNDAY AND HOSPITAL SATURDAY MOVEMENT.

Few things are better known to the majority of medical men than that the just and successful management of hospital relief for the poor is beset with a number of problems. Essentially, these problems are the same everywhere, turning largely on the difficulty of procuring funds for the adequate support of hospitals without depending supinely on the generous impulses of a few men, whereby the greater number of those on whom the burden ought to fall escape their obligations altogether, or without falling into the still more deplorable error of making the institutions a direct tax upon the State.

A notable contribution to the solution of these difficulties, however we may view the details he proposes, has lately been made by Mr. Henry C. Burdett, of London, whose interest in matters connected with the maintenance and management of hospitals, as well as the extent of his information concerning them, is not unknown on this side of the Atlantic. We refer to a paper recently read by him, apparently at a meeting of the councils of the Hospital Sunday and the Hospital Saturday Funds, of London, which, together with the discussion to which it gave rise, has reached us in the form of a pamphlet. At the outset, Mr. Burdett deals with the historical aspect of the movement, and he brings forward strong evidence in support of the view that Canon Miller is to be credited with having practically initiated it. With that matter, however, we have no present concern; but it is gratifying to note that the editor of the "Lancet" is conceded to have been chiefly instrumental in extending the operation of the system to London.

The writer of the paper makes some radical criticisms of the methods employed in behalf of the Hospital Saturday Fund, chiefly the underhanded way in which the collections are sometimes made, the appearance of dickering with the hospital authorities, and especially the cost of carrying on the work. Concerning the first of these points, he quotes as follows from a letter written by a member of the council: "The Saturday Fund goes to the workshops of London on the mere chance of finding some one who may be able to steal, as it were, occasionally a few minutes of the employer's time in coaxing his shop-mates to give him a contribution. It is always difficult to do this in a workshop when men's minds are fully occupied with their respective callings, and must hardly ever be done openly before the foremen or employers."

It appears that in London the hospitals profit by the Saturday Fund not altogether in proportion to the amount of charitable work they do, but to some extent, we infer, according to their willingness to give what Mr. Burdett looks upon as a *quid*

pro quo in the shape of "tickets." This, he thinks, must detract from the true spirit of charity in which the workingmen ought to make their contributions. In the debate, however, it was replied not only that this was not a legitimate inference, but that the policy in question was actually beneficial, inasmuch as "tickets" were thus put within the reach of the workingmen without their being subjected to the hardship of canvassing for letters among those qualified to grant them. It was urged, moreover, that there was no reason why the contributors to such a fund should not be entitled to "tickets" quite as much as individual subscribers to the funds of the hospitals. It seems to us that the plain inference to be drawn from this diversity of views is, that the "ticket" system is a thoroughly bad one, by whomsoever it may be administered. So far as we know, there is nothing of the sort in use in this country, and it is quite certain that the need of it has never been felt.

In regard to the expense of collecting the Saturday Fund, Mr. Burdett believes that it amounts to about one fifth of the sum collected—a proportion far in excess of that for the Sunday Fund, and even of that for the Saturday Fund in other English towns. But in this respect, as in all others, the members of the council present when Mr. Burdett read his paper professed their entire willingness to profit by any suggestions he might be able to make. The remedy he proposed consisted in the consolidation of the two councils—a measure that does not seem to have found favor with the meeting; and it is not clear that such a course would be attended with the great saving which he appeared to expect, while there is reason to suppose that a single council would prove awkward in operating two sets of machinery so diverse. It seems probable that the net gain from the Saturday Fund, although smaller, both absolutely and in proportion to the outlay, is really so much added to what the total would otherwise amount to.

THE TEACHING OF DERMATOLOGY IN FRANCE.

Of all the qualities, whether in an individual or in a nation, calculated to lead on to greatness or to the "recovery of lost perfection," the disposition to self-criticism is unquestionably one of the foremost. The French people, with all their undoubted greatness, have not generally shown this disposition to any great extent; indeed, they have usually seemed to be of the frame of mind of a certain assemblage of worthies who passed two resolutions: 1. That the saints should inherit the earth; 2. That they were the saints. It is doubly gratifying, therefore, to meet with such a token of amendment on the part of the French as is shown in a recent editorial article in the "Progrès médical."

The article treats more particularly of the decadence of French dermatology, especially as compared with that of the Vienna school, but the admission is made, quite without reserve, that the teaching of pædiatrics in Paris is decidedly in a bad way, and by implication something approaching the same indictment is brought against the way in which the other branches of medicine are handled.

The Hôpital Saint Louis, the writer recognizes, is still unri-

vaied in the magnitude of its special service, but that very fact, accompanied as it is by serious defects in turning the clinical facilities to account, leads him to liken it to a *congestion*; and he writes regretfully of the disorder and the dizzy rapidity that characterize the teaching. There is not room for the patients that ought to be received, there is not room for the museum, and the teaching force is wholly inadequate. The Bietts, the Cazenaves, the Devergies, and the Bazins are no more. M. Fournier is a man of great ability, but, primarily and above all else, he is a syphilidologist, and apparently a dermatologist only by force of circumstances. Give him free play (says the writer, in effect) in his chosen field, and let some one else teach dermatology. There is, undoubtedly, a good deal of force in this last suggestion, but it does not seem to us to strike at the root of the matter, for we believe Fournier to be quite equal to the occasion. But there is another feature which, if it is not remedied, will surely defeat any aspirations the French may have for enduring supremacy in dermatology; and that is the fact, as the writer in question shows, that practically there is no career in dermatology open to a young man in Paris. He may serve as an *interne*, but for a fixed and brief period only; after that he may become a hospital physician, but the chances are against his being assigned to the Saint Louis, except by the caprice of the system of rotation, and that only after the lapse of ten or fifteen years spent in the general medical service, during which time he has become disheartened, and has in great degree lost his familiarity with skin diseases, so that he finds himself obliged to learn dermatology *de novo*. This dreary outlook is sharply contrasted with the steady gradation that is readily within the reach of a promising man in Vienna.

According to our author, there is no single remedy for this state of things, but a number of reforms must be accomplished. The Saint Louis should be enlarged, dermatology should be made a branch by itself in the faculty, and, above all, the way should be made easy for young men who wish to devote themselves to the study and teaching of diseases of the skin. The latter end is to be attained by really specializing the hospital making appointments on its staff rest upon the test of a special *concours*, rather than subject to the accident of rotation. We have no doubt that our contemporary hits the nail on the head and we are persuaded that its article, if properly taken to heart by the profession and the hospital authorities in France, will prove to have pointed to the regeneration of French medicine.

MINOR PARAGRAPHS.

THE "WORLD" ON BEARDED WOMEN.

In its issue for September 22d, the "World" gave a full column or more to its medical department—all on bearded women and the electrolytic method of relieving them of their superfluous hairs. According to the "World," this process seems to have had almost as many discoverers as the telephone. Among these discoverers Dr. George H. Fox, Clinical Professor of Diseases of the Skin in the College of Physicians and Surgeons, figures prominently, and so much of the "World's" article as is not devoted to a sensational account of the various bearded women who have from time to time been on exhibition

is given up to a scarcely less sensational interview with that gentleman. Can it be because the "World" has a grudge against the College of Physicians and Surgeons that it thus persistently holds the members of its faculty up to virtual ridicule?

THE BOSTON CITY HOSPITAL REPORTS.

We lately commended the work done by the Boston City Hospital, and expressed our regret that there had been no recent issue of a volume of its excellent "Reports." We are glad to be able to say now, on the authority of a member of the medical staff, Dr. Robert T. Edes, that it is scarcely more than two years since the third volume appeared. It is edited by Dr. David W. Cheever, Dr. Oliver F. Wadsworth, and Dr. A. L. Mason, and may by had of Messrs. A. Williams & Co., Boston. It is a pleasure to learn that the series is continued.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 23, 1884:

DISEASES.	Week ending Sept. 16.		Week ending Sept. 2	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	32	17	44	11
Scarlet Fever.....	27	8	17	1
Cerebro-spinal meningitis.....	4	4	5	4
Measles.....	22	11	16	5
Diphtheria.....	29	17	33	17

The Cholera seems practically to have ceased its ravages in France, but the accounts are to the effect that it is still raging in Italy, and that there is an uncomfortable prevalence in certain Spanish towns.

Yellow Fever in New York.—Another man infected with yellow fever has found his way into New York, having eluded the quarantine, but the sanitary officials do not entertain the fear that the disease will be spread.

Suicide of a Medical Student.—We regret to have to announce that a member of the class at the Medical Department of the University of the City of New York committed suicide in a cab last week, the only motive, apparently, being a condition of depression occasioned by the hopeless illness of his mother and sister.

The Medical Society of the County of New York, at the meeting held on Monday, the 22d inst., had before it the applications of two gentlemen who had been homoeopathsists, and who had been graduated from homoeopathic schools. No final action was taken on the applications, but the names were referred back to the Comitia Minora.

Nominations for Officers of the Medical Society of the County of New York for the ensuing year were made at the meeting held on Monday, the 22d inst., as follows: For president, Dr. Daniel Lewis, Dr. Henry B. Sands, Dr. D. B. St. John Roosa, and Dr. Andrew H. Smith; for vice-president, Dr. Frank P. Foster and Dr. Laurence Johnson; for secretary, Dr. Wesley M. Carpenter; for assistant secretary, Dr. Charles H. Avery; for treasurer, Dr. Orlando B. Douglas; for censors, Dr. J. W. Howe, Dr. F. M. Weld, Dr. H. E. Crampton, Dr. J. H. Ripley, Dr. W. R. Gillette, Dr. F. R. S. Drake, Dr. A. S. Hunter, and Dr. H. T. Peirce.

A New English Medical Journal, to be called the "Medical Chronicle," is announced to make its appearance next month.

It will be published monthly at Manchester, and will be edited by James Niven, M. B., and W. J. Sinclair, M. D., in conjunction with a publishing committee, consisting of Dr. J. Thorburn, Dr. Charles J. Cullingworth, Dr. Julius Dreschfeld, Dr. James Hardie, Mr. Thomas Jones, Dr. D. J. Leech, Dr. David Little, Dr. D. Lloyd Roberts, and Dr. James Ross. It will be seen that this list includes the names of a number of gentlemen who are well known in America, and it must be said that the new journal will start under unusually favorable auspices. It is to be regretted, we think, that the title chosen for it is identical with that of a journal now published in Baltimore.

Mr. Lawson Tait, of Birmingham, England, by invitation, gave a clinic at Bellevue Hospital on Saturday morning, the 20th inst., in the course of which he removed the ovaries and the oviducts in two cases. The remarks which he made on the conditions that call for this operation were of great interest, and, as he kindly offered to write them out for this journal, we expect to be able to lay them before our readers in full in a future issue. The impression made by Mr. Tait on that occasion, as on every other on which he has appeared before the American profession, was to the effect that he was not only a most accomplished surgeon, but also a man of attractive personal character.

Dr. W. S. Playfair, of London, was to meet a large representation of the medical profession of New York and the neighboring cities last evening, at a reception to be given in his honor by Dr. Thomas Addis Emmet.

The American Gynecological Society will hold its ninth annual meeting at the Palmer House, in Chicago, on Tuesday, Wednesday, and Thursday, September 30th and October 1st and 2d. The programme includes the following papers: *Tuesday*.—Moot Points in regard to Inversion of the Uterus, by Dr. John C. Reeve, of Dayton, O.; Foreign Bodies in the Abdomen after Laparotomy, by Dr. Henry P. C. Wilson, of Baltimore; Abdominal Section; its Value and Range of Application, by Dr. C. D. Palmer, of Cincinnati; The Hygiene of Pregnancy, by Dr. Samuel C. Busey, of Washington; Rapid Dilatation of the Cervical Canal, by Dr. William Goodell, of Philadelphia; Cervical Fibroids as a Cause of Dystocia, and their Removal by Vaginal Enucleation, by Dr. Paul F. Mundé, of New York. *Wednesday*.—The President's Address; The Present Aspect of the Puerperal Diseases, by Dr. Albert H. Smith, of Philadelphia; A further Report upon Extra-uterine Pregnancy, embodying Six Cases, by Dr. T. Gaillard Thomas, of New York; A Case of Tubal Pregnancy, with Rupture of the Sac, by Dr. R. B. Maury, of Memphis; The Limits of Vaginal Hysterectomy for Cancer, by Dr. Paul F. Mundé, of New York; Some Remarks on the Occipito-posterior Position in Vertex Labors, with an Analysis of Thirty-five Cases, by Dr. Edward Warren Sawyer, of Chicago; A Rare and Fatal Form of Sepsis without Symptoms, by Dr. George J. Engelmann, of St. Louis. *Thursday*.—The Physiognomy of the Vulva as a Sequence of Anal Disease, and the Cause or Sustaining Cause of Uterine Disease, by Dr. Isaac E. Taylor, of New York; The Early History of the Treatment of Vesico-vaginal Fistule in the United States, and the Statistics of the Several Modes of Operating, by Dr. Nathan Bozeman, of New York; Periodical Symptoms in Uterine Disease, by Dr. George J. Engelmann, of St. Louis; Contributions to the Topographical and Sectional Anatomy of the Female Pelvis, by Dr. David Berry Hart, of Edinburgh (to be read by Dr. Alexander J. C. Skene, of Brooklyn); Fibro-myomata and Fibro-cystic Myomata of the Uterus—their Diagnosis, Prognosis, Pathology, and Treatment; with Cases and Specimens, by Dr. R. Stansbury Sutton, of Pittsburgh; On the Ring of Bandl, by Dr. William T. Lusk, of New York.

A Bad Case of "Snakes."—We have recently received a communication in which the following statements are made:

"When I state that after the death of a dog or person who has been bitten with a poison snake, on examination P. M. there will be found attached to the liver a snake of the same species of the one that bit the dog or person, and if the dog has been bitten twice, there will be two snakes, and in one instance the snake put out its tongue nobody who has never seen it or heard of it will believe it. Yet such is the fact."

"This is why a person or dog who has been bitten with a snake, feels the influence every year, at the time snakes awake up from their dormant state."

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 14, 1884, to September 20, 1884:*

CALDWELL, D. G., Major and Surgeon. Granted leave of absence for one month and twenty days, to commence about October 15, 1884. S. O. 95, Headquarters Division of the Missouri, August 16, 1884.

CRONKHITE, HENRY M., Captain and Assistant Surgeon. From Department of the Platte to Department of the Missouri. Par. 1, S. O. 215, A. G. O., September 13, 1884.

TAYLOR, ARTHUR W., First Lieutenant and Assistant Surgeon. From Department of the Missouri to Department of the Platte. Par. 1, S. O. 215, A. G. O., September 13, 1884.

WILSON, WILLIAM J., Captain and Assistant Surgeon. From Department of Dakota to Department of the East. Par. 1, S. O. 220, A. G. O., September 19, 1884.

GARDNER, J. DE B. W., Captain and Assistant Surgeon. From Department of Arizona to Department of the East. Par. 1, S. O. 220, A. G. O., September 19, 1884.

CORBUSIER, WILLIAM H., Captain and Assistant Surgeon. From Department of the East to Department of Arizona. Par. 1, S. O. 220, A. G. O., September 19, 1884.

LA GARDE, L. A., Captain and Assistant Surgeon. From Department of the Missouri to Department of Dakota. Par. 1, S. O. 220, A. G. O., September 19, 1884.

BARROWS, C. C., First Lieutenant and Assistant Surgeon. Granted one month's leave of absence, with permission to apply to the proper authority for an extension of one month. Par. 4, S. O. 86, Headquarters Department of Arizona, September 13, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending September 20, 1884:*

HARMON, G. E. H., Passed Assistant Surgeon. Ordered from Navy Yard, Norfolk, to Naval Academy, September 16th.

MCCLURG, W. A., Passed Assistant Surgeon. Ordered from Naval Academy to Naval Hospital, Philadelphia, Pa., September 16th.

LEACH, PHILIP, Passed Assistant Surgeon. Ordered from Hospital, Chelsea, Mass., to the Palos, September 16th.

COLES, J. W., Surgeon. Detailed as member and Recorder of Naval Examining Board, and ordered to Hospital, Philadelphia, September 16th.

DEER, E. Z., Passed Assistant Surgeon. Ordered to Navy Yard, New York, September 16th.

MACKIE, B. S., Surgeon. From training ship Jamestown to member and Recorder of Naval Examining Board, September 16th.

KINDLEBERGER, D., Medical Inspector. Relieved from Hartford, sick, September 18th.

DICKSON, S. H., Passed Assistant Surgeon. Permission to leave the United States, September 19th.

Society Meetings for the Coming Week:

TUESDAY, September 30th: American Gynecological Society (Chicago—first day).

WEDNESDAY, October 1st: American Gynecological Society (second day); Medical Society of the County of Richmond, N. Y.

THURSDAY, October 2d: American Gynecological Society (third day); New York Academy of Medicine ("The Three Ton-sils—Some Practical Suggestions as to their Structure, Function, and Diseases," by Francke H. Bosworth, M. D.; "The only Way of raising the Epiglottis in the Anæsthetic State," by Benjamin Howard, M. D., F. R. C. S. E.); Society of Physicians of the Village of Canandaigua, N. Y.

FRIDAY, October 3d: Practitioners' Society of New York (private).

SATURDAY, October 4th: Manhattan Medical and Surgical Society (private).

Letters to the Editor.**"AN ODD CASE."—PERIODICALLY RECURRING CONVULSIONS PRODUCED BY IMPACTED FÆCES.**

COLUMBUS, OHIO.

To the Editor of the New York Medical Journal:

SIR: In your issue of August 16th, Dr. Macauley reports a case in which persistent hiccoughing was due to constipation. *Apræpos* of his case, I will report the following, in which the muscular spasm was much more general:

March 14, 1884, I was called, about 2 P.M., to see Mrs. G., a widow, aged sixty-seven, but apparently much older. I found her in convulsions, involving nearly all the muscles of the body. The eyes were turned up, the eyelids half open and twitching, the limbs jerking about, and there was a slight tendency to opisthotonus. On extending the arms at right angles to the body, they would remain rigid, as in catalepsy, except some fibrillary twitching for some minutes, when they would gradually, and with increased twitching, sink to the side. She was entirely unconscious, and could not be aroused. She had been in this condition for three hours. Previous to this attack she had been about as well as usual, until within a day or two, when, not feeling quite so well as common, she had, on the day previous to my visit, taken a dose of salts, which had operated freely. She had a normal temperature and pulse. Had no headache, nor any other symptom of any centric disease. A most thorough examination failed to reveal any disease of any of the vital organs.

I prescribed bromide of potassium in large doses, and in about two hours she became conscious, the convulsions ceased, and she said she felt as well as usual. She complained of no pain or uneasiness anywhere, and I was at an utter loss to account for the attack. An examination of her urine showed it to be normal. The bromide was ordered continued in diminishing doses.

At eleven o'clock the next day the convulsions returned as before, and, notwithstanding the free use of the bromide, continued as long as on the previous day. This periodical recurrence of the attacks continued for four days, entirely unaffected by the varied sedatives and antispasmodics which were lavishly used. There being an entire absence of any indications of serious disease, and being impressed with the evident reflex character of the convulsions, I now, although her bowels had been reported as open daily, administered a full dose of croton-oil.

This operated very freely thirty or forty times, the nurse said, and on that day there was no return of the convulsions. But on the second day they returned as before, and at the same hour. She was again plied with antispasmodics, but without avail.

As the periodicity of the attacks was so marked a feature, I now administered quinine, thinking there might be a malarial element at the bottom of the trouble. This did no good.

Two weeks had now elapsed, with no perceptible change in the condition of the patient, except that she was weaker. I now recalled that I had treated her several years before for uterine proclivita. She had, however, had no trouble from that source since I had furnished her with a supporter, and had for a long time discontinued the use of the instrument. Suspecting that there might be some irritation at that point, I made a vaginal examination. The uterus was in place, and in the condition of senile atrophy. *But the rectum contained a mass of feces as large as a child's head.* The rest is soon told. The mass was broken down and removed in the usual way, and no more convulsions occurred.

The point of interest in the case is: There had been no history of constipation; the salts taken before I was called had operated freely; there was no constipation subsequent to the commencement of treatment; the croton-oil operated copiously and without scybala, yet the rectum was impacted with a tough mass, resembling blue clay in consistence, without producing any symptoms pointing to the seat of the trouble.

I am at a loss to account for the periodicity of the attacks of convulsions, except as a part of that common tendency of disease and of all functional activity.

Yours truly,

J. F. BALDWIN, M. D.

Proceedings of Societies.**CHICAGO MEDICAL SOCIETY.**

Meeting of September 15, 1884.

The President, Dr. D. A. K. STEELE, in the chair.

Congenital Malformation of the Stomach.—Dr. C. W. EARLE read a brief paper with this title, and related a case that he had recently observed in an infant which lived to be twelve days old. At the autopsy, no opening was found between the stomach and the duodenum, and there was no pylorus, but it was ascertained that biliary matter had been passed in the feces. The stomach was then shown.

Bony Tumor of the Female Pelvis.—Dr. EARLE also presented a specimen of this sort, weighing three pounds and a half. The tumor was regarded as a rare one, and was discussed informally.

National Sanitation.—Resolutions were presented by Dr. LISTON H. MONTGOMERY, calling upon the National Government to strengthen the hands of the National Board of Health in the work of preventing pestilential diseases and in investigations into their nature. The resolutions also provided for the appointment of a committee of seven to draft suitable resolutions to be presented to Congress.

After a full discussion, the resolutions were carried unanimously.

On motion of Dr. E. ANDREWS, a vote of thanks was passed to Dr. Vincent L. Hurlbut for the gift of a collection of three hundred valuable books and pamphlets to the Library Commit-

tee of the society, for the Chicago Public Library, in which there were now twelve hundred medical works.

The PRESIDENT appointed the following-named gentlemen to constitute the committee provided for in Dr. Montgomery's resolutions: Dr. O. C. DeWOLF, Dr. R. E. STAREWEATHER, Dr. L. H. MONTGOMERY, Dr. JOHN BARTLETT, Dr. J. H. ETHERIDGE, Dr. A. R. JACKSON, and Dr. J. H. HOLLISTER. Dr. H. A. Johnson, who would have been appointed on the committee, asked to be excused, on the ground that he was a member of the National Board of Health.

LISTON H. MONTGOMERY, M. D., *Secretary*.

BROOKLYN PATHOLOGICAL SOCIETY.

Meeting of June 12, 1884.

DR. ANDREW OTTERSON in the chair;

DR. A. H. P. LEUF, *Secretary*.

Acute Ulcerative Endocarditis.—Dr. A. H. BUCKMASTER read the history of a case, in which there was rupture of an aortic cusp, with renal embolism followed by hemorrhagic infarction, and showed the specimens.

A Pocket Urinary Test Case.—Dr. E. H. BARTLEY, lecturer on physiological and practical chemistry in the Long Island College Hospital, read the following paper, showed a specimen of the instrument, and illustrated its workings:

Several more or less successful attempts have been made, of late, to provide a ready means of studying the urine at the bedside. Notable among these is the preparation of test-papers saturated with various reagents, intended as tests for albumin and sugar, suggested by Dr. George Oliver.

Previous to having seen this suggestion, I had constructed for my own use a case for the pocket containing a test-tube, litmus test-papers, a urinometer, an alcohol-lamp, and a phial for Fehling's solution.

I have lately had made, by Mr. Haslam, of this city, a number of compact cases which are more complete than my first one, and which I present here to-night.

The case contains four compartments, one for litmus-papers cut in small strips, one for a test-tube containing a urinometer inclosed in a cloth bag for safety in carrying, and the other two containing phials holding powders intended as reliable tests for albumin and sugar. In addition to this, a little dropper is introduced for convenience as a pipette.

The case when shut is $4\frac{1}{2}$ inches long, $2\frac{1}{4}$ inches wide, and one inch thick, or of about the size of an ordinary pocket instrument-case.

This case is intended to give at the bedside the four principal factors in the chemical examination of the urine—viz., the reaction, the specific gravity, the presence or absence of albumin, and the presence or absence of sugar. These points being determined, together with the approximate quantity passed in twenty-four hours, the color, odor, etc., and the symptoms of the patient as a guide, we have most of the points for a diagnosis. Of course, it can not do away with the necessity for a microscopical examination afterward, but in many cases a question of doubt may be determined with something approaching certainty.

With the litmus-paper, the reaction, if alkaline, may be shown to be so from fixed alkalis or from fermentation by warming over a lamp until dry, when in the latter case it will return to the former red color.

The specific gravity, with the quantity passed in the twenty-four hours, gives much valuable information, as follows:

1. Quantity low, specific gravity high (above 1.025), color high: febrile urine.

2. Quantity high, specific gravity high (above 1.025), color light: suspect sugar.

3. Quantity high, specific gravity low (below 1.008), color light: diabetes insipidus.

4. Quantity low, specific gravity low (below 1.015), color light or dark, and containing albumin: suspect Bright's disease.

5. Quantity small, color light, specific gravity low, with cerebral symptoms: suspect uremia.

The quantity of solids passed in twenty-four hours may be found by multiplying the last two figures of the specific gravity by 2 or 2.3, which will give the solids in grammes contained in one litre (one quart). This result, multiplied by the number of litres, will give the solids passed in twenty-four hours.

The normal amount of solids passed is from sixty to seventy grammes. In apothecaries' measure the last two figures of the specific gravity very nearly represent the number of grains to the ounce. By multiplying the last two figures of the specific gravity by the number of ounces passed in the twenty-four hours, an approximate estimate of the number of grains is obtained. This should be between 900 and 1,200 grains. One half of the solids passed is usually estimated to be urea. The specific gravity can therefore be used to give the approximate amount of urea passed. Many other points may be determined by the use of the urinometer, such as the progress of fevers from day to day, etc.

The tests which I have selected for albumin and sugar have been chosen with a view to certainty of action and indications, and those which can be carried in the form of a fine powder.

Two powders are suggested as tests for albumin, both of which are delicate, and, with proper precautions, leave little to be desired as to certainty of indication.

One of these is a mixture of finely pulverized potassium ferrocyanide and citric acid, in the proportion of 3 to 2, although the proportion does not seem to be very important. As the mixture undergoes slight change in the course of some weeks, I prefer to keep the two ingredients in separate stock-bottles, and mix them in the phial at intervals of a fortnight. The decomposition above spoken of does not seem to interfere with the delicacy of the test after two months.

The method of using the test is to add a small quantity of the powder directly to about a drachm of the clear urine in the test-tube. The powder falls to the bottom and there dissolves, forming a concentrated solution; on agitation, the coagulated albumin may be readily seen. A preferable method is to dissolve the powder in a small quantity of water so as to make a strong solution; if it is not perfectly clear and transparent, warm gently (do not boil). The urine may now be delivered upon this reagent with the dropper, when, if any albumin is present, it will appear at the line of separation of the two liquids. The test is quite delicate.

The other test for albumin is made by mixing together one part of mercuric chloride, two parts and a half of potassium iodide, and four parts of citric acid, each to be pulverized and then shaken together. This powder dissolves in water to form a clear solution, upon which the urine may be poured. If the solution should contain any undissolved red iodide of mercury, a little more potassium iodide should be added. Other powders, or papers saturated with other reagents, may, of course, be carried in the phials, if so desired.

—The sugar test proposed is a mixture of one part of indigo-carmin, or sulphindigotate of sodium, and twenty parts of pure sodic carbonate. To use it, it is only necessary to add a very small quantity of the powder to the suspected urine, and heat over a lamp to boiling. If glucose is present, the blue color changes first to green, then violet, red, and finally yellow. On agitation of the tube, the indigo undergoes oxidation by the

oxygen of the air, and the colors mentioned reappear in the reversed order.

I know of no other ingredient likely to be found in urine which will give this indication. The indigo-carmin may be prepared by dissolving pure indigo in strong sulphuric acid, and adding sodium carbonate in sufficient quantity to just neutralize the acid and precipitate the coloring matter; filter, wash with sodic-carbonate solution, and dry the residue.

These tests are not new, but in the powder form I believe that they are more stable and more portable without interfering with their delicacy. A small quantity of the powder only is necessary, and the albumin tests have been so often discussed in the recent periodicals that I do not care to enter into the general discussion. I have found the case here presented of use in my own practice, and presume others may find it of service.

Pleurisy; Absorption of the Effusion; Phthisis; Nephritis.—Dr. THOMAS M. LLOYD, visiting physician to St. Peter's Hospital, related a case as follows:

John T., thirty-three years old, a widower, a cooper by trade, born in Ireland, was admitted into St. Peter's Hospital, March 17, 1884. He stated that he had had no sickness except small-pox, twenty-five years before. Two weeks before his admission, he was taken sick with a chill, fever, cough, and pain in the left side, and went to bed. There was pleurisy, with great effusion, and absence of respiratory murmur and complete flatness on percussion over the whole of the left side of the chest. The heart was pushed to the right of the sternum. The urine was acid, of the specific gravity of 1.009, and contained a trace of albumin. The quantity passed daily amounted to thirty-two fluidounces.

26th.—Respiratory murmur was discovered over the base of the chest, on the left side, posteriorly, where effusion still existed. This observation was confirmed by Dr. Segur and Dr. Martin. The explanation was supposed to be, that the normal respiratory sound was transmitted from the right lung. The respirations were from 28 to 32 to the minute.

The quantity of urine increased to sixty fluidounces under the use of diuretics. The temperature ranged from 101° to 103.4° F. until April 3d, when the respiratory murmur began to return over the left side.

April 15th.—The effusion was apparently absorbed.

18th.—Rheumatic pains developed in the legs, arms, and neck, and the temperature again rose to 103°.

May 1st.—The pains have been modified by treatment, but not entirely relieved. The patient is very anæmic, and his ears, conjunctivæ, and gums are very pale. Prolonged, high-pitched expiration is noted at the apex of the right lung.

5th.—He has become delirious and noisy at night; his evening temperature is 101°; he is passing forty-eight fluidounces of urine in twenty-four hours.

10th.—The urine contains ten per cent. of albumin, is cloudy and alkaline, of the specific gravity of 1.014, and shows granular and fatty casts. The daily quantity can not be ascertained. Delirium and stupor still continue.

11th.—He appeared brighter mentally, and said he felt much better. At 3 P. M. he was seized with convulsions, followed by coma and pulmonary œdema. He died at 12.10 A. M. on the 13th.

At the *autopsy*, both lungs were found bound down by pleuritic adhesions—the left one most decidedly. There was a deposit of recent lymph over a surface about three inches square on the left pleura, posteriorly, at the base. There was about an ounce of serum in the left pleural sac. The lower lobe of the left lung was condensed and much reduced in size, and bound to the upper lobe by firm fibrous adhesions. It weighed twenty-

one ounces. Tubercles and a small cavity were found in the upper lobe of the right lung, which weighed twenty-nine ounces. The heart was normal. The liver, which was fatty, weighed sixty-two ounces. Each kidney weighed seven ounces and a half.

The interesting points were: The continued fever after the almost complete absorption of the effusion; continued free urination to within a very short period before the convulsions, which were probably uræmic; the presence of tubercle on the side unaffected by the recent pleuritic disease.

Dilated and Hypertrophied Heart; Chronic Nephritis; Erysipelas.—Dr. LLOYD also related the following case:

John A., aged forty-nine, born in Finland, a sailor, and of late a longshoreman, was admitted into St. Peter's Hospital April 15, 1884. He had yellow fever seventeen years ago. For two years he has complained of pain on the left side and of forcible beating of the heart; the ankles have been cedematous occasionally, and he has had dyspnoea at times. Three months before his admission, while at the masthead in a severe cold wind, he was seized with sudden pain in the side, marked dyspnoea, and cough. Nine weeks afterward his legs began to swell. When he was admitted his legs were extremely swollen, and the scrotum was as large as a child's head. It had been punctured a few days before, and much serum was draining away daily. He had much dyspnoea. His urine was scanty, light yellow in color, acid, of the specific gravity of 1.011, but contained no albumin. The urates were in excess. The expansion of the chest was found diminished, and the cardiac impulse diffused. There was an apparent tumor in the right supra-clavicular space. There was percussion dullness from the second intercostal space to the sixth, and from the right edge of the sternum to the axillary line, on the left side, over a space ovoid in outline. The respiratory murmur was diminished on the right side anteriorly, at the base, and exaggerated above, with harsh, sonorous râles, on the left side, but diminished below, although to a less degree. Posteriorly, the respiratory murmur was feeble on both sides at the base of the chest, and there was some dullness on percussion over the regions where the respiratory murmur was defective. Forcible pulsation was felt as high as the third rib and to the left of the nipple line. Auscultation showed labored action of the heart, with loud closure of the semilunar valves, but no defined murmur.

Under treatment, the urine was increased to forty-eight fluidounces per diem, and the patient was much more comfortable, with comparatively little dyspnoea, until May 8th, when he had a chill, and a temperature of 105° F. Erysipelas developed on the thigh and the scrotum, he failed rapidly, and died on the 11th.

At the *autopsy*, the left lung was found bound down to the chest-wall from the third rib to the base by strong adhesions. The right lung also was adherent from the fourth rib to the base. The right lung weighed nineteen ounces, and the left one fifteen ounces. The bronchial tubes were thickened and dilated. The heart was dilated and hypertrophied, weighing when filled with clots thirty-seven ounces, and when empty twenty-three ounces. The pericardial fluid amounted to eight fluidounces. The heart occupied the region previously outlined by percussion. The liver, which had the nutmeg appearance, weighed seventy-two ounces. The kidneys weighed seven and a half and nine ounces.

The dilated and over-filled heart had operated to interfere with respiration in much the same way as an aneurysm. The corresponding lung was much reduced in size and weight.

Acute Tuberculosis.—Dr. LLOYD then related the following case:

Alfonso S., an Italian, aged thirty-five, who had been in this

country four months and a half, was admitted into St. Peter's Hospital, April 15, 1884. He was said to have vomited a large quantity of blood on rising in the morning two weeks before, but none since. He had had diarrhea for four days, with pain in the abdomen; also a chill every night, followed by fever. The urine continued free. Harsh respiration was found over the right lung, with tubular breathing and marked bronchophony at the base of the left lung. Afterward subcrepitant râles were heard, which increased in number and extended from day to day. The temperature ranged from 103° to 104° F. in the evening, and was not controlled by large antipyretic doses of quinine and salicylate of sodium. He failed rapidly, and died May 11th.

At the *autopsy*, both lungs were found tubercular throughout, and there was a small cavity in the left apex. The base of the left lung was greatly congested. Tubercles were found in the large intestine and through the greater portion of the small intestine, being most numerous near the ileo-cæcal valve; they were not found on the peritoneal surface of the intestine. The liver was fatty. The kidneys presented minute extravasations of blood, but no other lesions. Nothing was found in the stomach to account for the hemorrhage.

An interesting feature of the case was the marked absence of cough and expectoration, owing to the presence of diarrhea. The development of the disease was apparently quite rapid, although it was impossible to obtain a satisfactory history.

A Mammary Tumor, of doubtful character, was presented by Dr. JOHN HARRIGAN.

MEDICAL SOCIETY OF VIRGINIA.

Fifteenth Annual Meeting, held at Ruckley Springs, Tuesday, Wednesday, Thursday, and Friday, September 9, 10, 11, and 12, 1884.

Tuesday's Proceedings.

The meeting was called to order at 8.30 p. m., the President, Dr. J. EDGAR CHANCELLOR, of Charlottesville, in the chair. About one hundred and thirty members were present during the meeting, and at the opening session there were many ladies in attendance, including the wives and daughters of a number of the members.

Dr. GEORGE T. HARRISON, of New York, and Dr. F. M. ROBERTSON, of South Carolina, were present by invitation.

The Address of Welcome was delivered by Dr. M. G. ELLZEY, of Washington, D. C., the resident physician at the Springs during the summer season. It was courteously responded to by the President.

After prayer by the Rev. Dr. MALLECK, of Philadelphia, Pa., Dr. ROBERT I. HICKS, of Cassanova, delivered **The Address to the Public and Profession on Hygiene in Relation to the Private Family**. He spoke of the relationship of individual sanitation and public health, laid stress upon the importance of the germ theory, as enunciated by Pasteur, Koch, and others, and spoke of the diseases resulting from ignorance on the part of the people in regard to medical matters. Good quarantine laws should be enforced wherever or whenever an epidemic of a preventable disease existed. Legislation could do little else than enact laws, which, in most cases, were feebly executed, but, if carried out, would result in general good. Cleanliness of mind, body, and surroundings was the great principle of hygiene, both as to the individual and as to the public. Everybody ought to seek education on this subject, both for their personal interests and for the welfare of their communities. Hereditary influence, perhaps, controlled about 25 per cent. of diseases, but 74 or 75 per cent. of preventable diseases, according to a recent New York report, were due to such causes as damp, foul air,

insufficient food, poverty, and filth. Tubercle itself was simply an alteration of nutrition, resulting from neglect of trivial complaints and a disregard of sanitary laws. Gout, Bright's disease, dyspepsia, etc., were preventable diseases.

The location of the private residence next engaged attention. He said that pure air was antiseptic, and that from 1,200 to 2,000 cubic feet of it must pass through a room every two or three hours to make it wholesome for an adult to live in. The importance of ventilation, of light, of the removal of vegetable decomposing matters, etc., was pointed out. A person, by neglect, might not only produce disease in his own family, but spread it to his neighbors. Hence the economy to public health of enforcing personal hygiene.

On motion of Dr. BENJAMIN BLACKFORD, the address was ordered to be published.

Wednesday's Proceedings.

The Report on Advances in Anatomy and Physiology, prepared by Dr. HUGH T. NELSON, of Charlottesville, was read by Dr. LANDON B. EDWARDS, of Richmond, by request of the author, who was unavoidably absent. The object of the report was to present some recent but well-established additions to our knowledge of the physiology of the blood, the process of digestion, the intra-cranial nerve-system, the reporter confining his remarks on the latter subject to the sensory portion of the encephalon, since there had not recently appeared any additions to our knowledge of cerebral motor centers and their connections. The report bore upon the importance of alimentation in disease, especially recommending peptonized meats for the sick.

Medical Legislation.—Dr. WILLIAM C. DABNEY, of Charlottesville, Chairman of the Committee on Medical Legislation, reported that the committee had secured the passage of a bill by the Virginia Legislature establishing a State Board of Medical Examiners. The law was to go into effect January 1, 1885. It was not perfect, but was the best that could be secured. No person could hereafter enter upon practice in Virginia without first passing a satisfactory examination before this board. The penalty for violation of the law was a fine of \$500. The report was received and ordered to be published.

The President's Annual Address was then delivered. The President congratulated the society upon the large attendance at the meeting, the partial success of the Committee on Medical Legislation, etc., and spoke touchingly of the unusually large number of Fellows who had died during the year. He selected as his subject *the Origin and History of Ancient Medicine*. He incidentally urged further prosecution of medical legislation in regard to the Medical Examiners' Board and the State Board of Health, and advised that a history be written of the illustrious medical men of the State.

The address was well received, and ordered to be published.

Dr. JOSEPH A. WHITE, of Richmond, presented a volunteer paper on *Naso-Pharyngeal Obstruction and Hypertrophies in their Relation to Hearing*. It was a paper of the highest practical worth, suggesting many points of value to the practitioner. It was ordered to be published.

Election of Officers.—At the afternoon session the following-named gentlemen were elected officers for the ensuing year: Dr. S. K. JACKSON, of Norfolk, President; Dr. JESSE EVELL, Sr., of Hickory Grove, Dr. BENJAMIN BLACKFORD, of Lynchburg, and Dr. R. I. HICKS, of Cassanova, Vice-Presidents; Dr. LANDON B. EDWARDS, of Richmond, Recording Secretary; Dr. HUGH M. TAYLOR, of Richmond, Corresponding Secretary; and Dr. R. T. STYLL, of Richmond, Treasurer. The former Committee of Nominations, Committee on Publication, and Executive Committee were re-elected.

A night session, lasting from 8 p. m. until 2 a. m., was occu-

pied in the **Election of Members of the Board of Medical Examiners**, under the recent law establishing the State Board of Medical Examiners. The complimentary votes were for the two "Examiners at large." Dr. WILLIAM C. DABNEY, of Charlottesville, and Dr. FRANCIS D. CUNNINGHAM, of Richmond, received these compliments. Each of the ten Congressional districts made its own nominations, and most of those so nominated were elected as follows: *First Congressional District*: Dr. S. W. CARMICHAEL, of Fredericksburg; Dr. O. B. FINNEY, of Onancock; and Dr. W. W. DOUGLAS, of Middlesex County. *Second District*: Dr. THOMAS B. WAED, of Norfolk; Dr. L. LANKFORD, of Bowers; and Dr. JESSE H. PECK, of Elizabeth City County. *Third District*: Dr. R. A. LEWIS, Dr. CHARLES R. COLLEN, and Dr. O. A. CRENSHAW—all of Richmond. *Fourth District*: Dr. HUGH STOCKDELL, of Petersburg; Dr. WILLIAM J. HARRIS, of Nottoway County; and Dr. J. HERBERT CLAIBORNE, of Petersburg. *Fifth District*: Dr. RAWLEY W. MARTIN, of Chatham; Dr. WILLIAM L. ROBINSON, of Danville; and Dr. T. B. GREER, of Rocky Mount. *Sixth District*: Dr. HARVEY BLACK, of Blacksburg; Dr. H. GREY LATHAM, of Lynchburg; and Dr. OSCAR WILEY, of Roanoke. *Seventh District*: Dr. WILLIAM P. MCGUIRE, of Winchester; Dr. J. H. NEFF, of Harrisonburg; and Dr. H. T. NELSON, of Charlottesville. *Eighth District*: Dr. ALEXANDER HARRIS, of Jeffersonson; Dr. C. C. CONWAY, of Rapidan; and Dr. BEDFORD BROWN, of Alexandria. *Ninth District*: Dr. S. W. DICKINSON, of Marion; Dr. ROBERT J. PRESTON, of Abingdon; and Dr. R. D. HUFFARD, of Chatham Hill. *Tenth District*: Dr. G. D. MERRIWETHER, of Pedlar's Mills; Dr. Z. G. WALKER, of Brownsburg; and Dr. H. M. PATTERSON, of Monterey.

Thursday's Proceedings.

Communications.—After the society convened, president in the chair, a telegram from the first president (1870) was read in answer to one sent yesterday afternoon expressive of the feelings of the society in regard to his recent affliction. The telegram of Dr. ROBERT S. PAYNE, of Lynchburg, manifested the same zeal and anxious love for the society that he had so often proved by his attendance and active participation in the proceedings heretofore, and by his earnest good advice now expressed as the father of the society. A number of pleasurable and complimentary letters from invited guests outside the State as well as some from prominent men within the commonwealth were read, and ordered to be filed. Among these letters was one from Dr. WILLIAM W. PARKER, of Richmond, offering a resolution opposing eleemosynary medical colleges, which was adopted. Another was from Dr. GEORGE E. RIVES, of Rives, Prince George County, objecting to the power placed in the governor's hands to veto the action of this society as to the nomination of the members of the State Board of Medical Examiners.

A Memorial of the late Dr. J. Marion Sims was presented by Dr. SAMUEL B. MORRISON, of Brownsburg. It was eloquent in language, expressing the sympathy that members felt for the illustrious father of modern gynecology. On motion of Dr. URSHUR, the memorial was adopted by a rising vote and ordered to be recorded.

Dr. J. M. TONER, of Washington, D. C., was elected an Honorary Fellow of the society.

Dr. S. B. MORRISON, of Brownsburg, presented the **Report on Advances in Obstetrics and Diseases of Women**. It was a practical paper.

Dr. J. N. URSHUR thought want of success was often due to too harsh treatment. Soothing applications oftentimes had a better effect. Posterior cervical section was valuable in many cases. He had frequently performed it, with good results in every instance.

Dr. GEORGE T. HARRISON, of New York, read a paper, by invitation, on **The Modern Treatment of Wounds**, in which he specially advocated antiseptics.

Dr. MORRISON thought it best to let wounds alone. He had seen many cases during the war, and some since, in which the too anxious introduction of the finger or the probe did more injury than the wound itself.

Dr. HUNTER MCGUIRE, of Richmond, praised the paper read by Dr. Harrison, but he thought perhaps the good suggestions made in it in regard to antiseptics in general might lead some country practitioners to become dissatisfied with the means they had always at hand—good, pure country air. Lister's original recommendations undoubtedly added to the fatality of surgical operations. He was glad that plan had now been generally abandoned. "Antiseptic surgery" is undoubtedly good in great hospitals where the floors, the walls, and the beds were impregnated with septic poisons. But for country practitioners cleanliness was all that was essential—cleanliness of the person, of the patient, of the nurses, and of the surroundings.

Dr. I. H. STONE, of Lincoln, thanked Dr. McGuire for his practical remarks, which must give encouragement to every country practitioner. He cited several cases that had come under his care where antiseptics were not used and yet good results followed.

Dr. MORRISON urged the use of antiseptics in obstetric practice, so as to prevent puerperal fever, etc.

Dr. NEFF, of Harrisonburg, was glad Dr. McGuire had said what he had for his own encouragement. He used carbolic cotton, etc., as surgical dressings.

Dr. WILLIAM L. ROBINSON, of Danville, agreed with Dr. Morrison as to the importance of antiseptics.

The PRESIDENT thought there was no excuse nowadays for the neglect of antiseptic measures in the treatment of every case in obstetric practice.

Dr. MCGUIRE remarked that he was referring to the general field of surgical practice in his remarks. In obstetric practice he fully agreed as to the importance of antiseptics.

Dr. LANKFORD, of Southampton, thought it almost criminal for surgeons to do as he had seen some country doctors do—get off their horses with sweaty hands, etc., and go at once at the performance of a surgical operation without antiseptic precautions.

Dr. ALBAN S. PAYNE, of Markham, agreed with Dr. McGuire.

Dr. RIVES TATUM, of Harrisonburg, believed that Dr. Lankford was right.

Dr. JESSE EWELL, Sr., of Hickory Grove, who had been some fifty years in active practice, always used soap and water before doing a surgical operation or making a vaginal examination in obstetrical cases.

Dr. HUNTER, of Frederick County, said he always carried with him, when attending a case of infectious disease, a solution of carbolic acid in glycerin, with which to bathe his hands before making a vaginal examination of a pregnant or parturient woman.

Dr. ALEXANDER HARRIS, of Jeffersonson, read a paper on the **Therapeutic Virtues of the Fauquier White Sulphur Springs, Va.**, in which he showed that, of a large number of mineral waters of this country and Europe, only two contained ferric phosphates, and the Fauquier Springs water contained a larger percentage than these two. To this ingredient he attributed its great virtue in all the modern forms of neurasthenia, both in males and in females.

Honorary Fellows.—At the afternoon session, on motion of Dr. Hunter McGuire, Dr. GEORGE T. HARRISON, of New York, and Dr. F. M. ROBERTSON, of South Carolina, were elected Honorary Fellows.

Dr. ROBERTSON read a paper on **Rawley Springs**, which he had presented before his State society, and which had been published in the recent volume of its "Transactions."

Dr. HUNTER MCGUIRE, of Richmond, read a paper on **Intestinal Obstruction**, reviewing mostly the points of diagnosis. As to treatment, he urged the use of opiates hypodermically, rest, composure, etc. He strenuously opposed purgation. As soon as distinctive symptoms of invagination or the like could be made out, the abdomen should be opened and an attempt made to relieve the intestine of its unnatural position.

Dr. WILLIAM H. COGGESHALL, of Richmond, read a paper of great practical interest reviewing the subject of **Rectal Etherization**. It was evident that it was not so serviceable as the inhalation method; but, in some cases, where circumstances contra-indicated inhalation, ether should be given by the rectum. The great trouble to be apprehended was the setting up of bloody diarrhoea or dysenteric evacuations.

Dr. WILLIAM G. ROGERS, of Charlottesville, Chairman of the Committee on **Restriction of the Sale of Narcotic Poisons, especially Opium, its Products, Chloral, and Chloroform**, presented a paper showing great study and research, and advocating some definite legislation so as to lessen the danger to which the public was now exposed.

The Treasurer, in his report, stated that he had received \$1,016; that \$757.45 had been expended during the year, and that a balance of \$258.55 remained in the treasury.

Dr. JOSEPH A. WHITE, of Richmond, offered a resolution, which was adopted, appointing a committee of five members for the purpose of conferring with the physicians of North Carolina and West Virginia with a view to organizing a Tri-State Medical Society.

At the evening session Dr. M. A. RUST, of Richmond, read a volunteer paper on **Typho-Malarial Fever**. He showed that the disease was not a new one by any means—that from nearly the middle of the last century it had been recognized under other names, and in our younger days was familiarly known as "bilious fever," etc. It was neither typhus fever nor typhoid fever, nor was it a pure malarial fever, as the term malarial is generally used to indicate a special class of fevers of marsh miasmatic origin. It was a special fever which was common enough in our tide-water cities particularly. The recent epidemic of the so-called "Richmond fever" was nothing but typho-malarial fever. The thermometric curve was not like that characteristic of typhoid fever, nor like that of simple, uncomplicated malarial fever. In pure typhoid fever, the best treatment was "no medicine except to meet special indications." Sustain the vital powers by alcohol, beef-tea, etc. Boiled milk was the special diet. Quinine was useful in typho-malarial fever, but of no appreciable service in typhoid fever.

Dr. I. S. STONE, of Lincoln, presented a volunteer paper on the use of **Massage and Electricity in the Treatment of Chronic Hysteria and Allied Nervous Diseases from the Standpoint of the General Practitioner**. The plan of treatment he recommended was of special value in cases of functional trouble. He borrowed much of the advice given in the writings of Dr. Weir Mitchell as his guide. Exercise should be *passive* while the patient was in bed; and she should be kept in a quiet apartment, with a good nurse, without too much light, and allowed an abundance of nourishment, such as skimmed milk, etc., while properly conducted massage and properly directed currents of electricity were applied.

The meeting then adjourned to partake of the hospitalities extended by the proprietor of the Springs, in the form of a banquet, which was intensely enjoyed by the members until about two o'clock at night. Numerous toasts were given, and some of the speeches were eloquent.

Friday's Proceedings.

The society convened at 9 A. M. to enter upon the discussion of **Malarial Fever**. Dr. ROBERT B. STOVER, of Richmond, who had been appointed to open the discussion, was unable to be present, but forwarded his paper, which was read, by request, by Dr. UPSHUR. The writer thought the epidemic, of terrible severity and of great extent, in the city of Richmond during the past spring had resulted chiefly from the drinking-water used. The reservoir was mostly supplied by a canal, having its head some eight or nine miles above the city, in the James River, but into which, nearer the city, some marshy lands emptied their poisonous streams. There was also this other misfortune, that, in those parts of the city where the disease chiefly prevailed, earth was being upturned and mains were being laid. Then it must be remembered that the spring was a "forward" one, bringing out vegetation in advance of the usual season. He spoke of the pathological changes noticed in the kidneys, and thought that, if the disease was early enough attacked by appropriate remedies, such lesions could be averted. He generally began treatment with calomel and soda, followed up by tincture of iron and sulphate of quinine. Quinine was undoubtedly the truest friend in such cases. Morphine, in conjunction with quinine, was often needed to quiet nervous perturbations.

Dr. UPSHUR did not agree with Dr. Stover as to the water-supply having been the cause of the Richmond epidemic. The reservoir-water of that city had been chemically and microscopically examined by experts without the detection of any impurity. Besides, the disease prevailed in parts of the city not supplied by the reservoirs—where springs and wells were used. He thought the cause probably atmospheric. The disease was met with, for the most part, in children or young adults. It was not typhoid fever. He reported several illustrative cases.

Dr. WILLIAM L. ROBINSON, of Danville, read a paper descriptive of the effect of the epidemic wave of this same disease as it swept over his city. Quinine used hypodermically was beneficial. The milk diet was generally rejected from the stomach. Beef-tea, with its natural salts, was much better tolerated.

Dr. THOMAS J. MOORE, of Richmond, remarked that malaria had no known limits of territory. While it swept the valleys and the level lands, it always found a resting-place in marshy sections. It, nevertheless, under some untoward breeze, climbed mountain-heights and went with a vengeful furor into the delis beyond. Such was not the history of typhoid fever, nor were the symptoms alike. Heat, moisture, and vegetable decomposition were the essential factors of malarial disease—whether it appeared as the simple intermittent fever or as complex typho-malarial fever. Drainage of wet lands might be of service. Barriers might possibly be interposed between the affected region and the otherwise healthy homes by the planting of such trees as the now famous eucalyptus. He spoke at length of the two forms of malarial fever that caused the greatest alarm because of their fatality—the hemorrhagic and the "pernicious." In all grave cases he would use quinine hypodermically; and, if the nervous symptoms of excitement, etc., were great, would combine it with morphine. Warburg's tincture, similarly used, was very valuable. He had first seen it recommended by Dr. Metcalfe, of New York.

Dr. M. A. RUST, of Richmond, thought the sooner we dismissed the term typho-malarial fever from our terminology the better for us as practitioners. He would simply add to the remarks already made that the atmospheric air traveled ordinarily at the rate of about seven feet a second. Hence atmospheric germs, springing up at one point, could not remain long in one place, unless they were being continuously reproduced, and thus

lengthened their lines of infection by pressing winds. The term "typhoid fever modified by malarial poison" involved a theory that was not supported by fact. If we admitted such a theory, it was as well to admit the term typho-malarial fever as a proper one. But in his paper, read last night, he had shown that "typhoid fever must necessarily present all grades and shades of severity."

On motion, all papers not thus far disposed of were ordered to be referred to the Publishing Committee. Under this resolution a paper by Dr. JOSEPH A. WHITE, of Richmond, entitled Remarks, etc., about Cataract, with Report of Fifty-two Cases, and a paper by Dr. EDWARD E. FIELD, of Norfolk, on Yellow Chills—a Comparatively Recent Manifestation of Malaria, were referred, without reading, to the Committee on Publication.

On motion of Dr. JOSEPH A. WHITE, of Richmond, delinquents were allowed until November 10, 1884, to pay up their dues, so as to have their names appear in the Register of Fellows.

On nomination by the President, Dr. WILLIAM SELDEN, of Norfolk, was elected an Honorary Fellow.

Scarlet Fever was selected as the subject for general discussion at the next annual session, and Dr. THOMAS J. MOORE, of Richmond, was chosen to open the debate.

Dr. H. M. CLARKSON, of Haymarket, was elected to deliver the Annual Address to the Public and Profession during the session of 1885, at Alleghany Springs.

Mr. A. C. CALHOUN, proprietor of Alleghany Springs, on the line of the Norfolk and Western Railroad, fifty or sixty miles beyond Lynchburg, in the section known as Southwest Virginia, invited the society to meet there next year without personal charge to members or delegates as to hotel or other accommodations, except for the stages from the depot, which is not over two miles distant. The invitation was accepted.

At the Rawley Springs more than was expected was provided for the comfort and pleasure of the society.

Miscellany.

Infant Digestion.—In the July number of the "Archives of Pediatrics," Dr. H. R. Bigelow, of Washington, says:

"The question of infant growth is one of assimilation. Assimilation of food will depend upon the integrity of the digestive function. The digestive system of the new-born is not formulated at once, but develops in logical ratio with the expansion of other parts of the body. Its measure is the requirement necessitated by the elaboration of tissue. Tissue-growth is a slow process, demanding especial nourishment, and varied at each advance in age. The necessities of the child, both chemical and physiological, are not those of the adult, because each is adjusted with great exactness to the immediate environment. The excess of non-nitrogenous matter, which is an essential to adult life, is pernicious to the well-being of the infant. Muscles, when at work, consume principally hydrocarbonaceous aliments, and not albuminoid substances. In the infant there is no muscular exertion, and hence it draws more largely for its development upon the nitrogenous substances than upon the hydrocarbons. At birth the alimentary tract is short, the cæcum being very small, and the masticatory organs are absent. Biber says that the ptyalin appears only with the cutting of the first tooth. Reasoning from analogy, it is not improbable that the pancreatic and intestinal ferments are also inoperative until about the eighth month. Nature is not a spendthrift, and she would not call into useless action any function not demanded by the necessities of her own handiwork. With the eruption of the teeth a new era begins. Mastication presupposes increased development. Increase of development calls for increase of nourishment, and increase with variety in nourishments sets up new digestive processes, in which the ptyalin and the other ferments play an important part.

"The alimentary tract of the infant is exceedingly susceptible, so that nursing women have to be very careful in their diet. Now, if this tract is so impressionable as to feel any departure from a standard diet in the mother, how much more seriously will it suffer in the administration directly of unwholesome cow's milk—not unwholesome, perhaps, in the light of general use, but unwholesome for the limited infantile digestion. It may have an acid reaction, or it may have come from a cow in heat, or it may be tainted with certain vegetable substances obnoxious to the child. The natural food of the baby is its mother's milk.

"An intelligent study of human milk will lead up to a more just comprehension of the demands of infant digestion, and to a more perfect knowledge of a physician's duty in prescribing for such cases as are, unfortunately, deprived of the mother's breast. It would be a valueless encumbering of space, and an expenditure of time without profit, to cite one half the analyses that are matters of record. It best subserves the present purpose to view the main constituents of human milk in their relation to certain physiological principles. It is to be noticed, first, that woman's milk has an *alkaline* reaction, which persists for an indefinite period, and a specific gravity of about 1.0317. It contains water largely in excess (89.20 in 100 parts), milk-sugar, nitrogenous matter, fat, and salines. The albuminoids will vary in different women so largely that we can not affirm that any analysis is infallible. A fair average percentage would probably be about 4.84. The milk-sugar (6.997) is much greater than in cow's milk (4.92). These figures are only approximately correct. No two samples yield the same results. This variability in the composition of woman's milk, if not pathological, is a wise dispensation of nature to provide for the exigencies of each month of advancing age. Thus the function of the milk-sugar as a heat-producer is kept constantly in mind, while the absolute rate of nutrition may vary within wide limits, because the bodily heat must be preserved at all hazard. In fat, woman's milk exceeds that of the cow, but falls far below it in albuminoids. The ash, or mineral constituent of milk, is chiefly concerned in metamorphosis. The basic phosphate of sodium is invariably found in the blood, while the acid phosphate of potash is the chief constituent of the juice of the flesh. Phosphate of lime is intimately incorporated with the nitrogenous constituent principles. It is very generally admitted that the carbohydrates lead on to fat-production, through the co-operation of the nitrogenous and saline elements. Nitrogenous elements themselves, when in excess, may also serve as a source of fat. Nitrogenous matters do not, probably, undergo complete oxidation within the body; a portion of them is eliminated as urea. Fatty compounds are of higher value as force-producers, because they contain a quantity of hydrogen as well as of carbon free for oxidation. Pavy says that the value of nitrogenous compounds as force-producers depends upon the amount of unoxidized oxidizable elementary matter they contain. In human milk the percentage of nitrogenous matter to carbohydrates is about 1.45. About one fourth part of its casein is coagulable by acid. The *alkaline* reaction is *highly valuable*, since it serves to convert the casein into *soluble albuminoids* and soluble carbohydrates, which are great heat-producers. Writing upon this subject, Küss says: 'It is generally admitted (Moleschott, Voit) that an adult consumes 320 grammes of carbon and 21 grammes of nitrogen, or, in other words, 130 grammes of albuminoid elements, and 488 grammes of hydrocarbons and fats (fats 84, hydrocarbons 404); it follows that, in this case, the normal proportion in a mixed diet, of nitrogenous to non-nitrogenous aliments, is 1 to 3.7, while in milk, as well as in the egg, the proportion is 1 to 3, or even 1 to 2; in other words, the quantity of albuminates (nitrogen) is much larger, and of hydrocarbons (carbon) much smaller. This fact may be easily explained by referring to the part played by the hydrocarbons in regard to the production of force—muscular force especially. The adult draws his forces from the combustion of non-nitrogenous substances, the albuminates scarcely serving for this purpose. On the other hand, when the organism is in course of development, the nitrogenous substances are indispensable to the growth of the different tissues. It is therefore easy to see how mistaken is the common practice of condemning children to a diet containing a large quantity of starch and scarcely any nitrogen.'

"Woman's milk contains no starch. It may be conceded that, in

the adult, the ptyalin may continue its action in the stomach; that particles of unconverted starch may be transformed by the pancreatic and intestinal juices. In the infant this rule can not apply. The baby does not secrete ptyaline until the sixth or eighth month, *neither do the other juices, of pancreas and intestine, have any transforming power whatever before that period.* It is sheer ignorance to assert that small particles of starch can do no harm, since they undergo transformation in the intestine, when the truth is that they not only act as irritants, but pass out of the bowels unchanged. The attenuant of woman's milk is an important factor, of which we have little absolute knowledge. It is chiefly in consideration of this point that *cow's milk can not ever be safely substituted for that of the mother.* Before it can satisfactorily approximate to this great food of nature it must be radically transformed by some chemical process, which science has not yet developed. The addition of water to cow's milk will reduce the percentage of albuminoids into harmonious relationship with human milk, but it does not suffice to change the characteristics of the clot. To use starch as an attenuant is, of course, radically wrong.

"In view of these facts, it becomes a matter of the utmost interest to establish some definite principles of treatment, in cases where the mother is unable for any reason to nourish her child properly and sufficiently. There is no known process, chemical or mechanical, by which cow's milk alone can subserve this purpose. Up to six months of age, at least, the baby needs just those equivalents found within the mother's breasts—nothing more and nothing less. The compound must be *alkaline* in reaction; it must contain no *cane-sugar* (because cane-sugar must be first converted into grape-sugar before it can be assimilated; cane-sugar is frequently subjected to a kind of acetous fermentation, producing excess of acids in the infant stomach, so that bodily heat will diminish and disorders of respiration and circulation will follow), and no *starch*. It must be rich in heat-producers, although, as I have said before, the amount of albuminoids may vary greatly. Position has something to do with digestion. In some bad cases it will be found that, if the infant be placed in the usual position of a nursing child in its mother's arms, it will assimilate its food, when artificially fed, much more readily. In the nursing child a by no means inconsiderable amount of heat is derived from the mother's body. An artificially fed infant is deprived of this, so that there should be some compensatory action in its food. There have been many attempts made to overcome this difficulty, and our journals have been full of discussions upon the matter. It may be said that no artificially prepared food that does not meet all these requirements will be of permanent value in infantile therapeutics. What is needed is something rich in carbohydrates, with a proper admixture of albuminoids, salts, and moisture, free from starch and sugar, and alkaline in reaction."

Dr. Bigelow then gives notes of three cases of disease in infants, with disturbed digestion or assimilation, in which great benefit attended the use of Mellin's food. "I satisfied myself," he says, "by personal analysis of the constituents of the preparation, and found that it contained the principles which it seemed to me nature demanded, in exact combination, and more satisfactorily and more cheaply prepared than I could compound upon my own prescription."

A Naval Medical Examining Board, for the purpose of examining candidates for admission to the medical corps of the navy, will convene at the Naval Hospital at Philadelphia on October 1, 1884. There are at present several vacancies in the list of assistant surgeons, and successful candidates will be immediately appointed.

The Laws of the United States (*vide* Revised Statutes, Sections 1368, 1370, 1428, 1471, 1474) provide that "the active list of the medical corps of the navy shall consist of a surgeon-general, with the relative rank of commodore; fifteen medical directors, with the relative rank of captain; fifteen medical inspectors, with the relative rank of commander; fifty surgeons, with the relative rank of lieutenant-commander or lieutenant; and one hundred assistant surgeons, with the relative rank of master or ensign; and, further, that no person shall be appointed assistant surgeon until he has been examined and approved by a board of naval medical officers designated by the Secretary of the Navy, nor who is under twenty-one or over twenty-six years of age, nor who is not a citizen of the United States."

Applicants for examination and appointment in the medical corps will apply to the Hon. Secretary of the Navy for permission to appear before the medical examining board.

The application must be in the handwriting of the candidate, stating age and place of birth.

ORDER OF EXAMINATION.—1. *Physical.*—This will be thorough, and, in addition, the candidate will be required to sign a certificate that he is free from any accidental or constitutional defects, and without any predisposition to disease. 2. *Literary and Scientific.*—Familiarity with the branches taught in well-organized schools will be required, and this must include, at least, an elementary knowledge of Latin. Acquaintance with the natural sciences, ancient and modern languages, and the higher mathematics will be considered, and due credit given for proficiency in any of them. 3. *Professional.*—Oral and written examination will include anatomy, physiology, surgery, science and practice of medicine, obstetrics, diseases of women and children, chemistry, medical jurisprudence, materia medica and therapeutics, pharmacy, and hygiene. There will be also clinical examinations at a hospital, involving the use of the thermometer, laryngoscope, ophthalmoscope, and microscope as aids to diagnosis, and surgical operations upon the cadaver.

The board will expect candidates to present respectable testimonials of moral and professional standing. Appointments will be made as vacancies occur, in the order of merit in which candidates are reported by the board, when a vacancy is to be filled, but a qualified candidate not appointed within a year must be re-examined. A candidate found not qualified will not be permitted to reappear for examination within a year.

When no interruption occurs, the examination is usually completed within a week. No allowance can be made for the expenses of persons undergoing examination.

FORM OF APPLICATION. (To be in the handwriting of the applicant):

_____, 187__.

To the Hon. Secretary of the Navy:

SIR:

I respectfully make application for examination as to my qualifications for appointment as assistant surgeon in the United States Navy. I was _____ years of age on the _____ day of _____, 187__, and reside in _____, county of _____, and State of _____.

Very respectfully,

PAY TABLE.	At sea.	On shore duty.	On leave or waiting orders.
Fleet surgeons and engineers	\$4,400
Medical directors and medical inspectors at sea	4,400
Surgeons at sea:			
First five years after date of commission	2,800	\$2,400	\$2,000
Second five years after date of commission	3,200	2,800	2,400
Third five years after date of commission	3,500	3,200	2,600
Fourth five years after date of commission	3,700	3,600	2,800
After twenty years from date of commission	4,200	4,000	3,000
Passed assistant surgeons:			
First five years after date of appointment	2,000	1,800	1,500
After five years from date of appointment	2,200	2,000	1,700
Assistant surgeons:			
First five years after date of appointment	1,700	1,400	1,000
After five years from date of appointment	1,900	1,600	1,200

The Vaccination of School Children in Illinois.—At the regular quarterly meeting of the State Board of Health, held in the city of Springfield, July 2 and 3, 1884, the secretary, in his report to the board, made the following comments and suggestions:

With regard to further action concerning small-pox, in view of the probability of its epidemic spread from abroad, as shown by its increasing prevalence in London and elsewhere, and its frequent introduction into the State from neighboring States, I would suggest that it is desirable to call the attention of sanitary authorities and others to these facts and to the experience of the last few months, which shows that, when the disease is introduced into a community where vaccination and revaccination were not thoroughly carried out during the recent epidemic, there is still danger of serious trouble. It is also important that county superintendents, school boards, and others interested, should have their attention again directed to the fact that the *School-Vaccination Order of the board is permanent and continuous*, and that its thorough enforcement is expected, so as to prevent any accumulation of unprotected or imperfectly protected scholars, from term to term. To this end I think it necessary to again print and distribute copies of the Order, with necessary instructions, together with supplies of certificates and blanks for returns to be made through the county superintendents by the first of January next.

In view of the foregoing considerations, the board subsequently adopted the following resolution:

Resolved, That the increasing prevalence of small-pox in London and elsewhere, indicating a probable renewal of the epidemic tendency, and its frequent introduction into Illinois from neighboring States within the past few months, make it desirable that vaccinal protection be secured as fully as possible in every portion of the State; and to this end the secretary is hereby authorized to call the attention of sanitary authorities and others to the subject, and to take the necessary steps to push the further enforcement of the School-Vaccination Order of the board, so that all new scholars, and those who have not heretofore fully complied with its provisions, may be properly protected against small-pox before the advent of cold weather.

In accordance with this action of the board, county superintendents of schools, school directors, trustees, and teachers, are hereby reminded that the admission of any child to a public school in this State without presenting satisfactory evidence of proper and successful vaccination is prohibited.

The following extracts from opinions of the Attorney-General define the rights and duties of all concerned in this matter:

Under the Revised Statutes of Illinois, Chapter 126a, Section 2, broad duties are devolved upon the State Board of Health, and ample power is given to enable them to discharge such duties. They not only have the right, *but it is their duty*, to make any and all rules and regulations which they may deem necessary to preserve the public health. Such rules and regulations when promulgated *have the force and authority of law*, and are to be enforced, if necessary, by the entire power, including school officers, etc., of the State.

... As to the authority of school directors to enforce the rules of the State Board of Health in reference to vaccination, I have the honor to say that Section 2 of the act creating the State Board of Health declares that "it shall be the duty of all police officers, sheriffs, constables, and all other officers and employees of the State, to enforce such rules and regulations, so far as the efficiency and success of the board may depend upon their official co-operation." These are the words of the law, and it includes school directors with all other officers. In enforcing the orders of the Board of Health, of course the law will protect them in using any necessary means to carry out the orders, even to the extent, should it become necessary, *of excluding from the school those who refuse to comply*.

Based upon these opinions, the Hon. Newton Bateman, now president of the board, presented the following resolution, which was unanimously adopted at a meeting held January 19, 1882:

Resolved, That the power of the State Board of Health, under the law creating said board, to order the vaccination of all public-school children, is clear and unquestionable. The consequent duty of boards of school directors to see that such order is strictly enforced in their respective districts is equally clear, and the said order of the Board of Health is their sufficient warrant for so doing.

Should any board of directors refuse or neglect to carry out said order, they may be proceeded against for neglect of duty; and should any such board be prosecuted for enforcing said order, they may, if

necessary, employ counsel to defend them in such suit, and pay said counsel out of any school funds of their district not otherwise specifically appropriated.

The protection of the public health from the loathsome and deadly scourge of small-pox is a paramount obligation, and nothing can, or should, or will excuse school boards or other officers or persons concerned from doing their whole duty in the premises.

The following facts concerning the operation of the School-Vaccination Order during the winter of 1881-'82 are compiled from the Fifth Annual Report of the State Board.

When the School-Vaccination Order went into effect, January 1, 1882, nearly sixty-nine per cent., or over 490,000, of the enrolled scholars in Illinois were either entirely unprotected against small-pox by vaccination, or had again become susceptible through failure to revaccinate at the proper time. Within sixty days—that is, by the 1st of March, 1882—there was less than six per cent. of unprotected and susceptible remaining among those in attendance; and the frequency of small-pox and varioloid among public-school children had been lessened more than one third, while the mortality rate of cases was reduced from 16.5 per cent. to 3.3 per cent. On the one hand the number of cases was reduced owing to the general vaccinal protection; and, on the other hand, the cases which did occur were milder and less fatal, because of the modifying effect of vaccination. The small-pox reports made to the board from all parts of the State during the four years, 1880-'83, show that the deaths among *unvaccinated* school-children were at the rate of 48 in every 100 attacked; while the deaths among *vaccinated* school-children were only in the proportion of *nine tenths of one per cent.* of those attacked. It is difficult to conceive of a stronger argument than these figures present for the necessity of a thorough enforcement of proper and successful vaccination as a prerequisite to admission to the public-school room.

Canned Foods.—John P. Hawkins, C. S., Brevet Major-General, U. S. Army, says, in the "American Grocer":

"The army posts throughout the United States have been for a long period, now nearly twenty years, supplied with canned articles, fruits, meats, vegetables, and preserves. Many of the posts are located where it is not possible to cultivate gardens, either on account of poverty of the soil, lack of rainfall, or rigor of climate, and, as a consequence, there is hardly a military station in the land where officers and soldiers and their families do not habitually use canned foods, and, as a class, army people are without doubt the largest consumers of canned articles in proportion to their number of any other in the country. While one occasionally sees an article in a newspaper telling how some one has been taken sick by reason of having eaten something from a can, yet, in all my army experience (and for many years I have been chief commissary of a military department, and, as such, had charge of supplying posts with all their subsistence), I have never known or heard of a case of canned goods poisoning in the army.

"The canned foods used are not of any particular packing either. We buy a good article, and from any packer that will furnish a proper quality, and there is considerable competition among packers to furnish us. Nor are our canned foods purchased in any particular section of the country, but usually from the packer or manufacturer who converts the crude material into the canned article, and our points of purchase extend from Maine to Texas and from the Atlantic to the Gulf. So it will be seen that our army supply is drawn from the same sources that supply the people at large, and that civilians and our army consume the same canned articles and under the same circumstances. I recently inquired of our medical director, Lieutenant-Colonel John E. Summers, surgeon, U. S. Army, a careful and skilled observer in his duties, and of large experience in his army profession, whether he had ever known of a case of poisoning in the army which might be attributed to canned goods, or whether any of his medical officers at military posts had ever reported such a case to him. To both inquiries he answered, No; he had never known or heard of such a case. As in his official capacity he has been for many years in the constant receipt of formal reports concerning the health and mortality of all the posts throughout the country, and statements as to causes operating to influence the health of every command, it would certainly follow that, if ever there was a

suspicion on the part of a medical officer that any canned food was the cause of a sickness or a disorder, there would be every probability in favor of its being reported and known to him and to the entire medical profession of the army.

"A further important fact in this connection is that soldiers often report sick to the surgeon for very trifling ailments, and, as a class, they are under more watchful scrutiny than any other class of people; and so if a case of poisoning which could justly be attributed to canned goods were ever to occur among them, even if not fatal or serious, there would be but a small chance that it would not come to the knowledge of the post surgeon. It would be almost an impossibility that he would be ignorant of the case and the causes.

"Deductions from the foregoing may be fairly made that the reports of poisoning by eating canned food are not to be believed, or are only to be believed when it may have occurred by reason of the person having eaten from a can the food in which was evidently spoiled, and so spoiled that the appearance of the can would surely have indicated the unsound condition of its contents to a person exercising ordinary care. If a person buys tainted meat from the butcher and eats it, knowing it to be a little off, and is taken sick, he must blame himself for trifling with his health; and likewise, if he buys canned food of suspicious appearance, he must expect to pay in health for his carelessness or temerity. Therefore, having no apprehension as to the method of packing an article, whether in tin or in glass, whether soldered with the aid of an acid or soldered inside or outside the can, there is every reason to consider canned articles as good for food as any food can be. The experience of our army ought to be conclusive on this subject. And no person having a decent knowledge of what is good or bad, sound or unsound, could be misled into eating an improper article from a can any easier than he could be induced in eat a decayed potato or a tainted piece of butcher's meat."

The Health of Michigan.—We have been favored by the secretary of the Michigan State Board of Health, Dr. Henry B. Baker, of Lansing, with the following statement:

"Reports by observers in different parts of the State show the diseases which caused the most sickness in Michigan during the month of August (four weeks ending August 30), 1884, as follows:

Number of weekly reports received, 205.	For preceding month.	
Diseases arranged in order of greatest area of prevalence.	Per cent. of reports stating presence of disease.	Per cent. of reports stating presence of disease.
Diarrhœa.....	88	72
Intermittent fever.....	72	73
Rheumatism.....	68	68
Neuralgia.....	60	66
Consumption of the lungs.....	60	63
Cholera morbus.....	50	39
Bronchitis.....	49	47
Dysentery.....	48	29
Remittent fever.....	44	45
Cholera infantum.....	42	27
Tonsillitis.....	35	34
Erysipelas.....	32	28
Influenza.....	30	28
Inflammation of the bowels.....	26	20
Whooping-cough.....	23	27
Typho-malarial fever.....	22	10
Inflammation of the kidney.....	20	24
Diphtheria.....	14	8
Typhoid fever.....	12	7
Scarlet fever.....	11	11
Pneumonia.....	10	15
Inflammation of the brain.....	10	9
Puerperal fever.....	9	7
Cerebro-spinal meningitis.....	8	6
Membranous croup.....	5	5
Measles.....	5	8

"For the month of August, 1884, the reports indicate that diarrhœa, cholera infantum, typho-malarial fever, cholera morbus, and dysentery increased in area of prevalence.

"Compared with the average for the month of August in the six years 1877-1882, erysipelas, rheumatism, and bronchitis were more prevalent, and remittent fever, intermittent fever, dysentery, and cholera morbus were less prevalent in August, 1884.

"For the month of August, 1884, compared with the average of corresponding months for the six years 1879-1884, the temperature was lower, the absolute and the relative humidity and the day ozone were less and the night ozone more.

"Including reports by regular observers and others, diphtheria was reported in Michigan in the month of August, 1884, at twenty-seven places—namely, Alamo, Armada, Alpena, Au Sable, Bloomfield, Birmingham, Berlin, Detroit, East Saginaw, Flint, Grand Rapids, Groveland, Holly, Ishpeming, Kalamazoo, Leland, Maple Rapids, Manistee, Monro, McBride, Northville, Oakland, Pontiac, South Haven, Summit, Vassar, and Warren; scarlet fever at twenty places—Albion, Au Sable, Armada, Bridge-town, Cadillac, Columbiaville, Clayton, Detroit, Dorr, Fairfield, Grand Rapids, Hastings, Hazleton, Ionia, Jasper, Kalamazoo, Novi, Stanton, Swartz Creek, and Sand Beach; and measles at ten places—Detroit, Grand Rapids, Grand Haven, Kalkaska, Kalamazoo, Ludington, Manistee, Muskegon, South Haven, and Whitehall."

The Ventilation of Houses was one of the many interesting subjects discussed at a sanitary convention held in Ionia, Mich., last December, the proceedings of which have been issued in the form of a supplement to the "Report of the Michigan State Board of Health." Dr. J. H. Kellogg, of Battle Creek, introduced the subject, and dwelt upon the importance of systematic provisions for renovating the air of sleeping-rooms, etc. One of the speakers was inclined to contest the necessity of such measures, and doubted if carbon dioxide could reasonably be looked upon as deleterious, except when it was present in large quantities. He added that, even regarding it as highly injurious, complicated arrangements for getting rid of it were not needed. "All you've got to do," he said, "is to cut a hole in the wall at the floor, and let the gas run out of the room." The assistant secretary of the convention, Mr. Erwin F. Smith, of Lansing, subsequently criticised this speaker's views as follows:

"The gentleman has overlooked the law of the diffusion of gases, in obedience to which law gases in contact for any length of time must become intimately mingled. This would entirely prevent any such outward flow of the carbonic acid by its own weight as the gentleman would have us believe could easily be brought about by providing an outlet into the open air at or near the floor. He has also overlooked the fact that carbonic-acid gas is not the most injurious of the products of respiration. As stated by the lecturer, the organic matter thrown off from the skin and lungs is the most harmful product of respiration. This organic waste matter, when rebreathed, acts as a direct poison upon the animal economy. It is less in quantity than the expired carbonic acid, but occurs along with that, so that when we have established the presence, from expiration, of an excess of carbonic acid in any room, we have at the same time proved that a more deadly, if not so easily detected, enemy is also present. This organic waste matter rises with the warm expired air to the ceiling, whence, as it cools, it is gradually diffused downward. Those who have carefully examined our poorly ventilated State prisons have repeatedly had demonstrated to them by the sense of smell, if not otherwise, that the upper layer of air in a room occupied by large bodies of men becomes soonest charged with foul emanations. In sleeping-wards, where cells rise above each other in from three to five tiers, the impurity of the air, as shown by the sense of smell and general feeling of oppressiveness, increases as one ascends from one gallery to another, until, toward morning, on the uppermost gallery near the ceiling, the stench and oppressiveness of the air become almost intolerable; and this, too, in spite of the fact that in the State House of Correction, at Ionia, numerous openings have been provided in the outer walls near the floor for the express purpose of ventilation. It is also true, as I know by observation, that prisoners who sleep in ranges of cells near the ceiling complain more of headache, have less appetite, and eat considerably less food than those sleeping in cells near the floor. From these considerations I think it is apparent that a room can not be properly ventilated by simply making an out-door opening at or near the floor."

STUDENTS' NUMBER.

THE MEDICAL SCHOOLS

OF THE

UNITED STATES AND CANADA.

Herewith we give as much information as our space will allow concerning the non-sectarian medical schools of the United States and Canada. The arrangement is by States, in alphabetical order, and the different colleges in individual States are mentioned in the order of their age. In many instances more particulars might have been given with advantage, but, as lack of space has precluded our following this course, we have been careful to give, so far as we have been able to ascertain them, the names and addresses of the deans or other officers to whom application for further information may be made.

It affords us pleasure to acknowledge the kindness of college officials in providing us with data for this issue.

Alabama.

MEDICAL COLLEGE OF ALABAMA,

MOBILE.

We have not received the announcement for the session of 1884-'85.

FACULTY.—F. A. ROSS, M. D., *Materia Medica* and *Therapeutics* (emeritus); E. P. GAINES, M. D., *Physical Diagnosis* and *Diseases of the Chest*; GEORGE A. KETCHUM, M. D., *Theory and Practice of Medicine*; E. H. FOURNIER, M. D., *Materia Medica, Therapeutics, and Clinical Medicine*; W. H. ANDERSON, M. D. (Dean), *Physiology*; J. F. HEUSTIS, M. D., *Surgery*; CHARLES MOHR, Jr., *Lecturer on Chemistry*; GORONWY OWEN, M. D., *Obstetrics and Diseases of Women and Children*; CALEB TOXEY, M. D., *Anatomy*; W. H. SANDERS, M. D., *Diseases of the Eye and Ear, and Histology*; RHETT GOODE, M. D., *Lecturer on Clinical and Minor Surgery*; P. C. CANDIDUS, G. P., *Lecturer on Practical Pharmacy*; D. E. SMITH, M. D. (Adjunct), *Surgery*; E. W. AUZAL, M. D. (Adjunct), *Physiology*; W. B. PAPE, M. D. (Adjunct), *Obstetrics, etc.*; RHETT GOODE, M. D., *Demonstrator of Anatomy*; E. DICKSON, M. D., *Assistant Demonstrator*.

FEES.—Matriculation, \$5; lectures, both at college and hospital, \$75; dissecting, \$10; graduation, \$25. All students are required to take the dissecting ticket.

For further information address W. H. Anderson, M. D., Dean, No. 70 St. Francis Street, Mobile, Ala.

Arkansas.

MEDICAL DEPARTMENT OF

ARKANSAS INDUSTRIAL UNIVERSITY,

LITTLE ROCK.

FACULTY.—P. O. HOOPER, M. D. (President), *Practice of Medicine*; EDWIN BENTLEY, M. D., *Institutes and Practice of Surgery*; A. L. BREYSACHER, M. D., *Obstetrics and Diseases of Women and Children*; J. A. DIBRELL, Jr., M. D.,

Anatomy; JOHN J. McALMONT, M. D., *Materia Medica, Therapeutics, Hygiene, and Botany*; JAMES H. SOUTHALL, M. D., *Institutes of Medicine*; ROSCOE G. JENNINGS, M. D., *Clinical Surgery and Dermatology*; J. M. BOND, M. D., *Medical Chemistry and Toxicology*; L. P. GIBSON, M. D., *Demonstrator of Anatomy*; T. E. MURRELL, M. D., *Ophthalmology and Otology*; JAMES H. LENOW, M. D., *Diseases of the Genito-urinary Organs*; CLAIBORNE WATKINS, M. D., *Physical Diagnosis and Clinical Medicine*; LOUIS R. STARK, M. D., *Gynecology*; JOHN WATERS, M. D., *Clinical Medicine and Prosector of Anatomy*; LOUIS AUGSPATH, D. D. S., *Oral Surgery*; W. U. SIMONS, U. S. Signal Service, *Meteorology, etc.*

There is a voluntary three years' graded course.

FEES.—Professors' tickets, \$50; matriculation, \$5; demonstrator's ticket, \$5; hospital ticket, \$3; graduation, \$25.

Address R. G. Jennings, M. D., Secretary, Little Rock, Ark.

California.

COOPER MEDICAL COLLEGE,

SAN FRANCISCO.

This college is the successor to the Medical College of the Pacific.

FACULTY.—HENRY GIBBONS, M. D., *Principles and Practice of Medicine*; L. C. LANE, M. D. (President), *Surgery*; C. N. ELLINWOOD, M. D., *Physiology*; ADOLPH BARKAN, M. D., *Ophthalmology and Otology*; J. H. WYTHE, M. D., *Microscopy and Histology*; HENRY GIBBONS, Jr., M. D. (Dean), *Obstetrics and Diseases of Women and Children*; WILLIAM A. DOUGLASS, M. D., *Clinical Surgery*; J. O. HIRSCHFELDER, M. D., *Clinical Medicine*; CLINTON CUSHING, M. D., *Gynecology*; W. D. JOHNSTON, M. D., *Chemistry and Toxicology*; R. H. PLUMMER, M. D., *Anatomy*; C. H. STEELE, M. D., *Materia Medica and Therapeutics*; JOHN F. MORSE, M. D. (Adjunct), *Anatomy*; W. S. WHITWELL, M. D. (Adjunct), *Obstetrics*; CHARLES E. FARNUM, M. D., *Demonstrator of Anatomy*.

The regular course begins in June of each year, and terminates in October. The intermediate course begins in January, and continues until the 1st of May.

FEES.—Matriculation, \$5; lectures, \$130; Demonstrator's ticket, \$10; graduation, \$40.

Further information may be obtained from Henry Gibbons, Jr., M. D., Dean, 101 Dupont Street, San Francisco, Cal.

Canada.

The possession of an M. D. degree does not entitle the holder to practice in Canada. He must become registered. In all the provinces of the Dominion except Ontario the possession of a degree in medicine from a recognized university entitles the holder to register. In Quebec, graduates of the universities of the province must appear in person at the May or September meeting of the board, present their diplomas and swear to them. Registration is granted only at these periods. It is optional with the board whether the holder of a degree from a university outside the province of

Quebec can register without further examination. In some cases the additional test has been enforced. In *Ontario*, all but registered practitioners of Great Britain must pass the examination of the College of Physicians and Surgeons of the Province before registration. The examination is held every spring. In *Nova Scotia*, *New Brunswick*, and *Manitoba*, the provincial boards accept the degrees of Canadian universities without examination. *Prince Edward Island* and *British Columbia* have as yet no medical boards.

A graduate in medicine of an American college, in order to register in any of the Provinces of the Dominion, must (a), unless the holder of an academical degree, pass the matriculation examination of the board, (b) attend some one of the medical schools in order to complete the curriculum required by the boards, and (c) pass the professional examination.

MCGILL UNIVERSITY, FACULTY OF MEDICINE,

MONTREAL.

FACULTY.—JOHN WILLIAM DAWSON, LL. D., F. R. S. (Principal), Natural History; WILLIAM WRIGHT, M. D., *Materia Medica* and Therapeutics (emeritus); DUNCAN C. MCCALLUM, M. D., Midwifery and Diseases of Women (emeritus); ROBERT CRAIK, M. D. (Treasurer), Chemistry (emeritus); JOSEPH MORLEY DRAKE, M. D., Institutes of Medicine (emeritus); R. PALMER HOWARD, M. D. (Dean), Medicine; G. E. FENWICK, M. D., Surgery; G. P. GIRDWOOD, M. D., Chemistry; GEORGE ROSS, M. A., M. D., Clinical Medicine; WILLIAM OSLER, M. D. (Registrar), Professor of the Institutes of Medicine; THOMAS G. RODDICK, M. D., Clinical Surgery; WILLIAM GARDNER, M. D., Gynecology; FRANCIS J. SHEPHERD, M. D., Anatomy; FRANK BULLER, M. D., Ophthalmology and Otolaryngology; ARTHUR A. BROWNE, B. A., M. D., Midwifery and Diseases of Infancy; JAMES STEWART, M. D., *Materia Medica* and Therapeutics; GEORGE WILKINS, M. D., Medical Jurisprudence; D. P. PENHALLOW, B. Sc., Botany; R. L. MACDONNELL, B. A., M. D., Demonstrator of Anatomy and Lecturer on Hygiene; WILLIAM R. SUTHERLAND, M. D., Assistant Demonstrator and Curator; GEORGE W. MAJOR, B. A., M. D., Instructor in Laryngology; ALEXANDER D. BLACKADER, B. A., M. D., Instructor in Diseases of Children; T. WESLEY MILLS, M. A., M. D., Demonstrator of Practical Physiology and Histology; ROBERT J. B. HOWARD, B. A., M. D., Assistant Demonstrator of Anatomy.

The fifty-second annual session opened October 1, 1884, and will last six months. Students from the United States must pass the university matriculation examination.

REQUIREMENTS FOR GRADUATION.—Attendance on four six months' sessions in this or some other recognized school, or four years' study, including three such courses; eighteen months of attendance at a hospital approved of by the university; six months' practice in pharmacy; three months' attendance at an approved lying-in hospital, including the care of six cases of labor. The other requirements are substantially the same as in the larger colleges of the United States.

FEES.—First year, \$67; second year, \$92; third year,

\$87; fourth year, \$65; hospital fees, \$28; graduation, \$30; university matriculation, \$5.

For further information address Dr. William Osler, Registrar of the Faculty, 1353 St. Catherine Street, Montreal. See also the Students' Number of the "New York Medical Journal" for 1883.

TORONTO SCHOOL OF MEDICINE

(AFFILIATED WITH THE UNIVERSITY OF TORONTO AND THE UNIVERSITY OF VICTORIA COLLEGE).

We have not received the announcement for the session of 1884-'85. Last year the faculty was as follows:

FACULTY.—W. T. AIKENS, M. D., LL. D., Principles and Practice of Surgery and Clinical Surgery; H. H. WRIGHT, M. D., L. C. P. & S., U. C. (Secretary), Principles and Practice of Medicine and Clinical Medicine; J. H. RICHARDSON, M. D., M. R. C. S. Eng., Descriptive Anatomy; UZZIEL OGDEN, M. D., Midwifery and Diseases of Women and Children; JAMES THORBURN, M. D., Edin. and Toronto Univ., *Materia Medica* and Therapeutics; M. BARRETT, M. D., Physiology; W. W. OGDEN, M. B., Midwifery (adjunct) and Medical Jurisprudence and Toxicology; M. H. AIKENS, M. B., M. R. C. S. Eng., Surgery (adjunct) and Primary Anatomy; W. OLDRIGHT, M. D., Medical Jurisprudence (adjunct) and Sanitary Science; L. MCFARLANE, M. B., Anatomy (adjunct) and Demonstrator of Anatomy; GEORGE WRIGHT, M. B., *Materia Medica* and Therapeutics (adjunct); J. E. GRAHAM, M. D., L. R. C. P. Lond., Practice of Medicine (adjunct) and Clinical Medicine and Dermatology and Pathology; R. A. REEVE, M. D., Diseases of the Eye and Ear; THOMAS HEYS, Chemistry; HENRY MONTGOMERY, B. Sc., Botany and Zoology; A. H. WRIGHT, M. B., M. R. C. S. Eng., Demonstrator of Normal Histology; JOHN FERGUSON, M. B., L. F. P. S. Glasgow, Assistant Demonstrator of Anatomy.

Address Dr. H. H. Wright, Secretary, corner of Sherbourne and Gerrard Streets, Toronto.

ROYAL COLLEGE OF PHYSICIANS AND SURGEONS

(MEDICAL DEPARTMENT OF QUEEN'S UNIVERSITY),

KINGSTON.

Not having received this year's announcement, we reproduce the following from our Students' Number for 1883:

FACULTY.—FIFE FOWLER, M. D., L. R. C. S. Edin. (President), Theory and Practice of Medicine; MICHAEL LAVELL, M. D. (Registrar), Obstetrics and Gynecology; MICHAEL SULLIVAN, M. D., Principles of Practice and Surgery; ALFRED S. OLIVER, M. D., *Materia Medica*, Therapeutics, and Pharmacy; THOMAS R. DUPUIS, M. D., F. R. C. P. S., K., and M. R. C. S. Eng., Descriptive Anatomy; THE PROFESSORS OF CHEMISTRY AND BOTANY IN QUEEN'S UNIVERSITY, Chemistry, Practical Chemistry, and Botany; KENNETH N. FENWICK, M. D., M. R. C. S. E., Institutes of Medicine; CHAMBERLEN A. IRWIN, M. D., Medical Jurisprudence; C. H. LAYELLE, M. D., L. R. C. P. S. K., Ophthalmic and Aural Surgery and Practical Anatomy; H. J. SAUNDERS, M. D.,

M. R. C. S. E., Clinical Surgery; JAMES MCCAMMON, M. D., M. R. C. S. E., Clinical Medicine; W. H. HENDERSON, M. D., M. R. C. S. E., Histology; ———, Sanitary Science; JOHN HERALD, M. A., and EDGAR FORRESTER, M. A., Associate Demonstrators of Anatomy.

FEES.—Registration, \$5; the different courses \$4 to \$12; each examination, \$10.

HALIFAX MEDICAL COLLEGE

(MEDICAL DEPARTMENT OF THE UNIVERSITY OF HALIFAX).

THE announcement for the session of 1884-'85 has not reached us. The following appeared in our Students' Number for 1883:

FACULTY.—R. S. BLACK, M. D., L. R. C. S. Edin. (President), Obstetrics (emeritus); ALEX. P. REID, M. D. (Dean), L. R. C. S. Edin., L. C. P. & S. Canada; ARCHIBALD LAWSON, M. D., M. R. C. S. England, Principles and Practice of Medicine and Clinical Medicine; WM. B. SLAYTER, M. D., M. R. C. S. L., F. O. S. London, L. R. C. P. England, Obstetrics and Diseases of Women and Children; EDWARD FARRELL, M. D., Principles and Practice of Surgery and Clinical Surgery; JOHN F. BLACK, M. D., *Materia Medica* and Therapeutics and Clinical Surgery; JOHN SOMERS, M. D., F. R. M. S., Physiology; GEORGE L. SINCLAIR, M. D., New York, M. D. Univ. Halifax, Anatomy; D. A. CAMPBELL, M. D., C. M. (Adjunct), Anatomy; H. McD. HENRY, LL.B., Medical Jurisprudence.

Lecturers.—E. JENNINGS, M. D., Dermatology; T. R. ALMON, M. D., Diseases of Children; D. DEW. HARRINGTON, M. D., Medical Jurisprudence; W. TOBIN, F. R. C. S. Ireland, Ophthalmology and Otology.

Instructors.—MR. W. H. WADDELL, Practical Chemistry; A. W. H. LINDSAY, M. D., M. B. Edin., Microscopy; C. E. PUTTNER, Ph. M., Practical Pharmacy; DR. CAMPBELL and DR. LINDSAY, Demonstrators of Anatomy.

FEES.—Medical jurisprudence, practical chemistry, practical pharmacy, microscopy, and botany tickets, \$6 each; practical anatomy ticket, \$8; other tickets, \$12 each; registration, \$2 (perpetual, \$5). Address F. J. Black, M. D., Registrar, 49 Granville Street, Halifax, N. S.

FACULTY OF MEDICINE,

UNIVERSITY OF BISHOP'S COLLEGE,

MONTREAL.

FACULTY.—F. W. CAMPBELL, M. D., L. R. C. P. Lond. (Dean), Principles and Practice of Medicine; J. B. EDWARDS, Ph. D., D. C. L., Practical Chemistry (emeritus); R. A. KENNEDY, M. D., C. M., Obstetrics and Diseases of Children; J. PERRIGO, M. D., C. M., M. R. C. S. Eng., Surgery; J. B. MCCONNELL, M. D., C. M., *Materia Medica*; CASEY A. WOOD, C. M., M. D., Pathology; GEORGE E. ARMSTRONG, M. D., Physiology; JAMES C. CAMERON, M. D., C. M., M. R. C. P. I. (Registrar), Medical Jurisprudence; THOMAS SIMPSON, M. D., Hygiene; E. H. TRENHOLME, M. D., C. M., B. C. L., Gynaecology; J. T. DONALD, M. A., F. C. S., Chemistry; H. L. REDDY, M. D., L. R. C. S. E., L. R. C. P. L.,

Medical Jurisprudence; A. LAPHORN SMITH, M. D., M. R. C. S. Eng., Botany; JOSEPH BEMROSE, F. C. S., Lecturer on Practical Chemistry; ALEXANDER PROUDFOOT, M. D., C. M., Lecturer on Diseases of the Eye, Ear, and Throat; D. D. GAHERTY, C. M., M. D., Anatomy; J. LESLIE FOLEY, C. M., M. D., Curator.

The fourteenth session began October 1, 1884, and will continue until the end of March, 1885. A preliminary examination is required.

FEES.—Separate tickets, \$6 and \$12; practical chemistry, \$12; practical anatomy, \$6; practical histology, \$16; enregistration, \$2; hospital tickets and clinical lectures, \$8 to \$12. The foregoing are for one course. Graduation, \$20.

For further information address Dr. F. W. Campbell, Dean, 10 Phillips Place, Beaver Hall.

TRINITY MEDICAL SCHOOL

(IN AFFILIATION WITH THE UNIVERSITY OF TRINITY COLLEGE, THE UNIVERSITY OF TORONTO, AND THE UNIVERSITY OF MANITOBA),

TORONTO.

FACULTY.—WALTER B. GEIKIE, M. D., C. M., F. R. C. S. E., L. R. C. P. Lond. (Dean), Principles and Practice of Medicine and Clinical Medicine; J. FULTON, M. D., C. M., M. R. C. S. Eng., L. R. C. P. Lond., Principles and Practice of Surgery and Clinical Surgery; J. E. KENNEDY, M. D., *Materia Medica* and Therapeutics; H. ROBERTSON, M. B., M. R. C. S. Eng., Anatomy; J. ALGERNON TEMPLE, M. D., C. M., M. R. C. S. Eng., Obstetrics and Diseases of Women and Children; THOMAS KIRKLAND, General Chemistry and Botany; C. W. COVERNTON, M. D., C. M., M. R. C. S. Eng., Sanitary Science; FRED. LE M. GRASETT, M. B., C. M. Edin. Univ., F. R. C. S. Eng., M. R. C. S. Eng., Medical Jurisprudence; W. T. STUART, M. D., C. M., Practical Chemistry; CHARLES SHEARD, M. D., C. M., M. R. C. S. Eng., Physiology and Histology, Normal and Pathological; GEORGE S. RYERSON, M. D., L. R. C. P., L. R. C. S. Eng., Ophthalmology, Otology, and Laryngology; LUKE TESKEY, M. D., C. M., M. R. C. S. Eng., Demonstrator of Anatomy; G. A. BINGHAM, M. D., C. M., M. B., Assistant Demonstrator.

The winter session began October 1st, and will continue six months.

Address Dr. Walter B. Geikie, Dean, 324 Jarvis Street, Toronto.

FACULTY OF MEDICINE OF

LAVAL UNIVERSITY,

MONTREAL.

FACULTY.—J. P. ROTTOT, M. D., Medicine and Clinical Medicine; E. P. LACHAPELLE, M. D. (Secretary), Physiology and General Pathology; A. LAMARCHE, M. D., Descriptive Anatomy; A. RICARD, M. D., *Materia Medica*; A. DAGENAIS, M. D., Obstetrics; J. A. LARAMÉE, M. D., Clinical Medicine; A. T. BROUSSEAU, M. D., Surgical Pathology and Clinical Surgery; C. M. FILIATRAULT, M. D., Medical Jurisprudence; N. FAFARD, M. D., Clinical Surgery (also Chemistry *ad interim*); E. BERTHELOT, M. D., Practical Anatomy; S. LACHAPELLE, M. D., Hygiene; H. E. DESROSNIERS, M. D.,

Toxicology; S. DUVAL, Diseases of Children (clinical—also Botany *ad interim*); A. A. FOUCHER, Diseases of the Eye and Ear; A. BRODEUR, M. D., Histology and Operative Surgery.

Address Dr. E. P. Lachapelle, Secretary, 132 rue St. Laurent, Montreal.

Colorado.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF DENVER.

FACULTY.—H. K. STEELE, M. D. (Dean), Principles and Practice of Surgery and Clinical Surgery; F. J. BANCROFT, M. D., Clinical Surgery—Fractures and Dislocations; J. C. DAVIS, M. D., Operative Surgery and Surgical Pathology; H. A. LEMEN, M. D., Principles and Practice of Medicine and Clinical Medicine; C. M. PARKER, M. D., Clinical Medicine—Fevers and General Diseases; W. H. WILLIAMS, M. D., Diseases of Women and Children; A. STEDMAN, M. D., Obstetrics and Puerperal Diseases; CHARLES DENISON, M. D., Diseases of the Chest and Climatology; S. A. BONESTEEL, C. M., M. D., Descriptive and Surgical Anatomy; S. A. FISK, M. D., Descriptive and Topographical Anatomy; W. E. WILSON, M. D., *Materia Medica* and Therapeutics; J. H. KIMBALL, M. D. (Secretary), Physiology and Diseases of the Mind and Nervous System; J. W. GRAHAM, M. D., Medical Jurisprudence; W. P. HEADDEN, Ph.D., Chemistry; E. C. RIVERS, M. D., Lecturer on Ophthalmology; H. H. HOWLAND, M. D., Lecturer on Laryngoscopy and Rhinoscopy; L. T. DUBIN, M. D., Demonstrator of Anatomy.

The fourth annual session began October 1, 1884, and will close on the last Wednesday in March, 1885.

FEES.—Matriculation, \$5; lecture course, \$5; laboratory fees, \$15; dissection, \$5; graduation, \$30.

Address Professor H. K. Steele, Dean, Denver, Col.

Connecticut.

MEDICAL DEPARTMENT OF YALE COLLEGE,

NEW HAVEN.

We have not received the announcement for the session of 1884-'85. Last year the faculty was as follows:

FACULTY.—BENJAMIN SILLIMAN, M. D., Chemistry; MOSES C. WHITE, M. D., Pathology; C. A. LINDSLEY, M. D. (Dean), Theory and Practice of Medicine; LEONARD J. SANFORD, M. D., Anatomy; WILLIAM H. CARMALT, M. D., Surgery; JAMES K. THACHER, M. D., Physiology; T. H. RUSSELL, M. D., *Materia Medica* and Therapeutics; FRANK E. BECKWITH, M. D., Obstetrics and Diseases of Women and Children.

Lecturers.—WILLIAM O. AYRES, M. D., Nervous Diseases; HENRY P. STEARNS, M. D., Insanity; S. HARTWELL CHAPMAN, M. D., Diseases of the Throat and Ear; SAMUEL B. ST. JOHN, M. D., Ophthalmology; WILLIAM H. HOTCHKISS, M. D., Demonstrator of Anatomy; T. MITCHELL PRUDEN, M. D., Normal Histology; HENRY FLEISCHNER, M. D., Dermatology; HERBERT E. SMITH, M. D., Chemistry.

The system of instruction embraces a three years' graded

course. A preliminary examination is required of those who have not a degree in letters or science from a recognized institution, or have not passed the examination for admission to Yale College.

FEES.—Matriculation, \$5; each year's tuition, \$125; graduation, \$30.

Address Professor C. A. Lindsley, Dean.

District of Columbia.

NATIONAL MEDICAL COLLEGE

(MEDICAL DEPARTMENT OF COLUMBIAN UNIVERSITY),

WASHINGTON.

FACULTY.—A. Y. P. GARNETT, M. D. (President), Clinical Medicine (emeritus); GRAFTON TYLER, M. D., Theory and Practice of Medicine (emeritus); N. S. LINCOLN, M. D., Surgery (emeritus); J. FORD THOMPSON, M. D., Surgery; W. W. JOHNSTON, M. D., Theory and Practice of Medicine; A. F. A. KING, M. D. (Dean), Obstetrics and the Diseases of Women and Children; EDWARD T. FRISTOE, LL. D., Chemistry and Toxicology; WILLIAM LEE, M. D., Physiology; ELLIOTT COUES, M. D., Ph. D., Anatomy; D. WEBSTER PRENTISS, M. D., *Materia Medica* and Therapeutics; A. C. ADAMS, M. D., Demonstrator of Anatomy; G. N. ACKER, M. D., Demonstrator of Practical Physiology and Pathological Histology; BENJAMIN G. POOLE, M. D., Assistant Demonstrator of Anatomy and Prosector in Anatomy; W. P. LAWVER, M. D., Demonstrator of Practical Chemistry.

The sixty-third course will begin October 6, 1884, and continue until March 1, 1885. Three graded courses are required.

FEES.—Full course of lectures, \$100; single tickets, \$15; practical anatomy, \$10; matriculation, \$5; examination fee, primary branches, \$20; examination fee, final branches, \$10.

Address A. F. A. King, M. D., Dean, 726 Thirteenth Street, Washington, D. C.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF GEORGETOWN.

FACULTY.—FLDOARDO HOWARD, M. D. (emeritus), Obstetrics and Diseases of Women and Infants; JAMES E. MORGAN, M. D. (emeritus), *Materia Medica*, Therapeutics, and Medical Jurisprudence; THOMAS ANTISEL, M. D. (emeritus), Chemistry and Toxicology; SAMUEL C. BUSEY, M. D. (emeritus), Theory and Practice of Medicine and Clinical Medicine; JOSEPH TABER JOHNSON, M. D. (President), Obstetrics and Diseases of Women; CARL H. A. KLEINSCHMIDT, M. D., Physiology; JOHN B. HAMILTON, Surgery; J. W. H. LOVEJOY, M. D. (Dean), Theory and Practice of Medicine; M. G. ELLZEY, M. D., Chemistry and State Medicine; FRANK BAKER, M. D., Anatomy; G. L. MAGRUDER, M. D., *Materia Medica* and Therapeutics; SWAN M. BURNETT, M. D., Ophthalmology and Otology (clinical); ETHELBERT C. MORGAN, M. D., Laryngology (clinical); LOUIS KOLIPINSKI, M. D., Demonstrator of Anatomy, and Curator.

The thirty-sixth regular course began Monday, September 22, 1884, and will continue until April 25, 1885.

FEES.—Lectures, \$100; matriculation, \$5; demonstration, \$10.

For further information apply to J. W. H. Lovejoy, M. D., Dean, No. 900 Twelfth Street, N. W., Washington, D. C.

MEDICAL DEPARTMENT OF HOWARD UNIVERSITY,

WASHINGTON.

THE announcement for the session of 1884-'85 has not been received. Last year the faculty was as follows:

FACULTY.—THOMAS B. HOOD, M. D. (Dean), Principles and Practice of Medicine; CHARLES B. PURVIS, M. D. (Secretary), Obstetrics and Diseases of Women and Children; NIEL F. GRAHAM, M. D., Principles and Practice of Surgery; DANIEL S. LAMB, M. D., Descriptive and Surgical Anatomy; WILLIAM H. SEAMAN, M. D., Chemistry; JOHN E. BRACKETT, M. D., Materia Medica and Therapeutics; ROBERT REYBURN, M. D., Physiology and Medical Jurisprudence; N. WHITCOMB, D. D. S., Dental Surgery and Operative Dentistry; ———, D. D. S., Dental Mechanism and Metallurgy; CLARENCE R. DUFOUR, Ph. D., Pharmacy and Botany; E. A. BALLOCH, M. D., Demonstrator of Anatomy; M. G. JENSON, M. D., D. D. S., Demonstrator in Dentistry.

This college is open to all without regard to sex or race.

FEES.—Matriculation, \$10; dissection, \$5; incidental expenses, \$20; graduation, \$30.

Address Charles B. Purvis, M. D., Secretary, No. 1118 Thirteenth Street, N. W., Washington, D. C.

MEDICAL DEPARTMENT OF THE NATIONAL UNIVERSITY,

WASHINGTON.

THE first regular course begins October 6, 1884, and continues until the last Thursday in April.

FACULTY.—J. T. WINTER, M. D. (President), Materia Medica and Therapeutics; H. H. BARKER, M. D. (Dean), Obstetrics and Diseases of Women and Children; T. E. McARDLE, M. D., Surgery; S. S. ADAMS, M. D., Theory and Practice of Medicine; G. W. COOK, M. D., Physiology; G. W. WEST, M. D., Anatomy; J. MORRISON, M. D., Ph. D., F. R. A. S., Chemistry and Toxicology.

Evidence of a preliminary education is required, and the course is graded.

FEES.—Lectures, \$100; demonstrator, \$10; matriculation, \$5.

Address H. H. Barker, M. D., Dean, 1116 H Street, Washington, D. C.

Georgia.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF GEORGIA,

AUGUSTA.

FACULTY.—L. A. DUGAS, M. D., LL. D., Surgery (emeritus); JOSEPH A. EVE, M. D., Obstetrics and Diseases of

Women and Children; G. W. RAINS, M. D., LL. D., Medical Chemistry and Pharmacy; HENRY F. CAMPBELL, M. D., Surgery and Gynecology; DE SAUSSURE FORD, M. D., Anatomy and Operative Surgery; EDWARD GEDDINGS, M. D. (Dean), Physiology and Pathology; R. C. EVE, M. D., Practice of Medicine; G. C. DUGAS, M. D., Materia Medica and Medical Jurisprudence; T. R. WRIGHT, M. D., Demonstrator of Anatomy; W. H. DOUGHTY, JR., M. D., Assistant Demonstrator.

There is an optional graded course. The session extends from the first Monday in November to the 1st of March.

FEES.—Lectures, \$75; matriculation, \$5; demonstrator, \$10; graduation, \$30. Two beneficiary students are admitted from each congressional district of the State.

ATLANTA MEDICAL COLLEGE,

ATLANTA.

FACULTY.—A. W. GRIGGS, M. D., Practice (emeritus); W. F. WESTMORELAND, M. D., Principles and Practice of Surgery; W. ABRAM LOVE, M. D., Physiology; V. H. TALIAFERRO, M. D., Obstetrics and Diseases of Women and Children; A. W. CALHOUN, M. D., Diseases of the Eye, Ear, and Throat; J. H. LOGAN, M. D., Chemistry; H. V. M. MILLER, M. D., LL. D. (Dean), Principles and Practice of Medicine, Lecturer on Clinical Medicine; W. S. ARMSTRONG, M. D., Anatomy, Lecturer on Clinical Medicine; J. S. TODD, M. D., Materia Medica and Therapeutics, Lecturer on Clinical Medicine; JAMES A. GRAY, M. D. (Proctor), Lecturer on Venereal Diseases; D. H. HOWELL, M. D., Lecturer on Minor Surgery; C. F. BENSON, JR., M. D., Demonstrator of Anatomy; R. O. COTTER, M. D., Assistant in Eye, Ear, and Throat Diseases.

The twenty-seventh annual course of lectures will begin on the 9th of October, 1884, and close on the 1st of March, 1885. There is an optional graded course.

FEES.—Full course, \$75; practical anatomy, \$10; matriculation, \$5; graduation, \$30. Gratuitous tickets (not including matriculation, practical anatomy, or graduation), will be issued to one student from each congressional district of the State.

For further information address James A. Gray, M. D., Proctor, Atlanta, Ga.

SOUTHERN MEDICAL COLLEGE,

ATLANTA.

Nor having received the announcement for the session of 1884-'85, we publish the following from our Students' Number for 1883:

FACULTY.—W. G. OWEN, M. D., Principles and Practice of Medicine (emeritus); T. S. POWELL, M. D., Obstetrics and Diseases of Women and Children, and Lecturer on Medical Ethics; R. C. WORD, M. D., Physiology and Lecturer on Hygiene; G. G. CRAWFORD, M. D., Operative and Clinical Surgery; W. PERRIN NICOLSON, M. D. (Dean), Descriptive and Special Anatomy; JOHN T. JOHNSON, M. D., Principles and Practice of Surgery; G. G. ROY, M. D., Materia Medica and Therapeutics, and Lecturer on Toxicology;

A. G. HOBBS, M. D., Diseases of the Eye, Ear, and Throat; W. D. BIZZELL, M. D., Principles and Practice of Medicine; J. A. BURNS, Chemistry.

FEES.—Matriculation, \$5; full course, \$75; demonstrator's fee, \$10; graduation, \$30.

For further information address W. Perrin Nicolson, M. D., Dean, P. O. Box 234, Atlanta, Ga.

Illinois.

RUSH MEDICAL COLLEGE,

CHICAGO.

THE announcement for the session of 1884-'85 has not been received. The following appeared in our Students' Number for 1883:

FACULTY.—J. ADAMS ALLEN, M. D., LL. D. (President), Principles and Practice of Medicine; DeLASKIE MILLER, Ph. D., M. D., Obstetrics and Diseases of Children; MOSES GUNN, M. D., LL. D., Principles and Practice of Surgery and Clinical Surgery; JOSEPH P. ROSS, M. D., Clinical Medicine and Diseases of the Chest; WILLIAM H. BYFORD, M. D., Gynecology; EDWARD L. HOLMES, M. D., Diseases of the Eye and Ear; HENRY M. LYMAN, M. D., Physiology and Diseases of the Nervous System; JAMES H. ETHERIDGE, M. D. (Secretary), Materia Medica and Medical Jurisprudence; CHARLES T. PARKES, M. D., Anatomy; WALTER S. HAINEs, M. D., Chemistry, Pharmacy, and Toxicology; JAMES NEVINS HYDE, M. D., Skin and Venereal Diseases; NORMAN BRIDGE, M. D., Hygiene and (Adjunct) Principles and Practice of Medicine.

A gradation of study is recommended and provided for, and those graduated after a three years' course receive a certificate of honor. Instruction in dentistry is included in the curriculum.

FEES.—Matriculation (annual), \$5; course of lectures, \$75; dissection, \$5; practical chemistry, \$5; final examination, \$30. Anatomical and chemical material "at cost price."

Address Professor James H. Etheridge, Secretary, 1634 Michigan Avenue, Chicago.

COLLEGE OF PHYSICIANS AND SURGEONS,

OF CHICAGO.

WE have received no announcement for the session of 1884-'85. The following appeared in our Students' Number for last year:

FACULTY.—A. REEVES JACKSON, M. D., Surgical Diseases of Women and Clinical Gynecology; SAMUEL A. McWILLIAMS, M. D., Clinical Medicine, Diseases of the Chest, and Physical Diagnosis; DANIEL A. K. STEELE, M. D., Orthopædic Surgery; LEONARD ST. JOHN, M. D., Demonstrations of Surgery and Surgical Appliances; CHARLES WARRINGTON EARLE, M. D., Obstetrics; HENRY PALMER, M. D., Operative Surgery, Clinical Surgery, and Surgical Pathology; R. L. REA, M. D., Principles and Practice of Surgery and Clinical Surgery; FRANK E. WAXHAM, M. D., Diseases of Children; JOHN E. HARPER, M. D., Ophthalmology and Clinical Diseases of the Eye; W. E. QUINE,

M. D., Practice of Medicine; J. J. M. ANGEAR, M. D., Principles of Medicine; A. W. HARLAN, D. D. S., Dental Surgery; W. A. YOHAN, M. D., Inorganic Chemistry; ALBERT E. HOADLEY, M. D., Descriptive Anatomy; PINCKNEY FRENCH, M. D., Surgical Anatomy; F. B. EISENBOCKIUS, M. D., LL. B., Medical Jurisprudence; C. C. P. SILVA, M. D., Therapeutics; OSCAR A. KING, M. D., Diseases of the Mind and Nervous System; ROMAINE J. CURTISS, M. D., State Medicine and Hygiene; E. E. HOLROYD, M. D., Physiology; W. K. HARRISON, M. D., Medical Chemistry; J. T. JELKS, M. D., Surgical Diseases of the Genito-urinary System; R. U. HALL, M. D., Demonstrator of Anatomy.

Lecturers.—E. P. MURDOCK, M. D., Gynecology; L. H. BURNETT, M. D., Surgical Anatomy; H. P. NEWMAN, M. D., Obstetrics; BOERNE BETTMAN, M. D., Ophthalmology and Otology; JAMES HUGHES LETCHER, M. D., Principles and Practice of Surgery; G. FRANK LYDSTON, M. D., Genito-urinary Diseases; JAMES G. REID, D. D. S., Dental Anatomy and Physiology; C. B. GIBSON, Demonstrator of Inorganic Chemistry.

FEES.—Matriculation (paid annually), \$5; lectures, \$50; dissecting ticket, \$10; graduation, \$30.

Address D. A. K. STEELE, M. D., Secretary, 1801 State Street, Chicago, Ill.

WOMAN'S MEDICAL COLLEGE,

OF CHICAGO.

THIS year's announcement not having been received, we reublish the following from our Students' Number for last year:

FACULTY.—W. GODFREY DYAS, M. D., F. R. C. S., Theory and Practice of Medicine (emeritus); G. C. PAOLI, M. D., Materia Medica and Therapeutics (emeritus); T. DAVIS FITCH, M. D., Gynecology (emeritus); WILLIAM H. BYFORD, M. D. (President), Gynecology; CHARLES WARRINGTON EARLE, M. D. (Treasurer), Diseases of Children and Clinical Medicine; ISAAC N. DANFORTH, M. D., Pathology and Renal Diseases; HENRY M. LYMAN, M. D., Theory and Practice of Medicine; DANIEL R. BROWER, M. D., Diseases of the Nervous System, Medical Jurisprudence, and Clinical Medicine; SARAH HACKETT STEVENSON, M. D., Obstetrics; DAVID W. GRAHAM, M. D. (Secretary), Surgery; PLYM S. HAYES, M. D., Chemistry and Toxicology; W. J. MAYNARD, M. D., Dermatology; W. T. MONTGOMERY, M. D., Ophthalmology and Otology; E. FLETCHER INGALS, M. D., Diseases of the Chest and Throat; F. L. WADSWORTH, M. D., Physiology and Histology; MARIE J. MERGLER, M. D. (Associate), Gynecology; WALTER L. DORLAND, M. D., Materia Medica and Therapeutics; MARY E. BATES, M. D., Lecturer on Anatomy; EUGENE S. TALBOTT, M. D., D. D. S., Dental Surgery; JOHN O. HOBBS, M. D., Demonstrator of Anatomy; JENNIE E. HAYNER, M. D., Lecturer on Hygiene; ROBERT S. HALL, M. D., Clinical Lecturer on Midwifery; EMMA M. NICHOLS, M. D., Assistant in Physiology and Lecturer on Histology; HOMER N. THOMAS, M. D., Assistant in Diseases of the Chest and Throat; ELIZA H. ROOT, M. D., ISABEL R. COPP, M. D., Assistants in Clinical Medicine; ANNETTE S. DOBBIN, M. D., Assistant Demonstrator of Anatomy.

FEES.—Matriculation, \$5; general ticket, \$50; demon-

strator's ticket, \$5; chemical laboratory ticket, required but once, \$5; graduation, \$30.

Address D. W. Graham, M. D., Secretary, 101 Warren Avenue, Chicago, Ill.

QUINCY COLLEGE OF MEDICINE (MEDICAL DEPARTMENT OF CHADDOCK COLLEGE),

QUINCY.

THE announcement for this year has not been received. The following appeared in our Students' Number last year:

FACULTY.—C. R. S. CURTIS, M. D. (Dean), Principles and Practice of Surgery; M. F. BASSETT, M. D., Principles and Practice of Medicine; VIRGIL McDAVITT, M. D., Obstetrics and Diseases of Women; WILLIAM A. BYRD, M. D., Clinical Surgery; L. H. COHEN, M. D., Chemistry and Toxicology; HENRY HATCH, M. D. (Registrar), Anatomy and Clinical Medicine; R. WOODS, M. D., Diseases of the Eye and Ear; CAREY B. ELLIS, M. D., Physiology and Hygiene; M. ROONEY, M. D., Clinical Medicine; HUGO ERICHSON, M. D., Diseases of the Mind and Nervous System; (vacancy), Materia Medica and Therapeutics; GEORGE CARLEY, Ph. D., Pharmacy; D. BRYAN BAKER, M. D., Demonstrator of Anatomy.

All applicants must present evidence of a good English education.

First course pupils will be examined on and be expected to give especial attention to anatomy, physiology, chemistry, and materia medica. Second and third course students will be particularly examined in the practical branches.

FEES.—Matriculation, \$5; professors' tickets, \$40; demonstrator's ticket, \$10; examination, \$25.

Address C. R. S. Curtis, M. D., Dean, or Henry Hatch, M. D., Registrar, Quincy, Ill.

Indiana.

FORT WAYNE COLLEGE OF MEDICINE,

FORT WAYNE.

Women are admitted.

FACULTY.—R. W. THRIFF, M. D., Puerperal Diseases and Diseases of Children (emeritus); CHRISTIAN B. STEMEN, M. D. (Dean), Surgery and Clinical Surgery; JAMES S. GREGG, M. D., Surgery and Clinical Surgery; GEORGE W. McCASKEY, Ph. B., M. D., Diseases of the Throat, Lungs, and Heart; FREDERICK S. C. GRAYSTON, M. D., and JOSEPH L. GILBERT, M. D., Theory and Practice of Medicine; I. ELLIS LYONS, M. D., Obstetrics; KENT K. WHELOCK, M. D., Diseases of the Eye and Ear; CHARLES R. DRYER, M. D., Chemistry and Toxicology; A. E. VANBUSKIRK, M. D., Anatomy and Clinical Surgery; J. H. DAVISSON, M. D., Materia Medica and Therapeutics; WILLIAM P. WHEBY, M. D., M. R. C. P., Diseases of Women; NORMAN TEAL, M. D., Orthopaedic Surgery and Clinical Surgery; WILLIAM SCOTT, M. D., Genito-urinary and Rectal Diseases; W. H. BELL, M. D., Nervous and Mental Diseases; F. R. BLOUNT, M. D., Diseases of Children; MILES F. PORTER, M. D., Physiology; J. T. WOODS, M. D., Lecturer on General Fractures; G. B. STEMEN, M. D., Assistant in the Chemical Laboratory.

The sixth annual session began September 16th, and will close March 1st.

REQUIREMENTS FOR GRADUATION.—Dissection for one session, practical instruction in chemistry, and hospital attendance, besides the usual requirements. The average on monthly examinations affects the candidate's final standing.

FEES.—Matriculation, \$5; lectures, \$40; dissection, \$5; laboratory, \$5; hospital, \$5; graduation, \$25.

Address Professor C. B. Stemen, Dean, 66 Calhoun Street, Fort Wayne, Ind.

CENTRAL COLLEGE OF PHYSICIANS AND SURGEONS,

INDIANAPOLIS.

FACULTY.—CHARLES D. PEARSON, M. D., Diseases of the Nervous System; W. S. HAYMOND, M. D., Principles and Practice of Surgery; JOHN MOFFETT, M. D., Obstetrics; R. E. HAUGHTON, M. D., Surgical Pathology, Operative and Clinical Surgery, and Medical Jurisprudence; G. C. SMYTHE, M. D. (Dean), Principles and Practice of Medicine and Sanitary Science; JOSEPH EASTMAN, M. D. (Secretary), Diseases of Women and Clinical Surgery; R. FRENCH STONE, M. D., Materia Medica and Therapeutics, and Clinical Medicine; JOHN A. SUTCLIFFE, M. D., Anatomy and Genito-urinary Diseases; S. E. EARP, M. D., Chemistry and Toxicology; J. O. STILLSON, Physiology and Diseases of the Eye and Ear; W. H. THOMAS, M. D., Demonstrator of Anatomy and Lecturer on Osteology; CANADA BUTTON, M. D., Prosecutor to the Chair of Anatomy; JOHN B. LONG, M. D., Assistant Demonstrator of Anatomy.

The regular session began October 1, 1884, and continues till March 1, 1885.

A preliminary examination is required of all who do not present evidence of a good English education. There is a voluntary three years' graded course.

FEES.—Matriculation, \$5; laboratory ticket, \$5; professors' tickets, \$40; demonstrator's ticket, \$5; hospital tickets, \$6; graduation, \$25.

Address G. C. Smythe, M. D., Dean, Indianapolis, Ind.

HOSPITAL MEDICAL COLLEGE,

EVANSVILLE.

FACULTY.—G. B. WALKER, M. D. (Dean), Obstetrics and Diseases of Women; A. M. OWEN, M. D. (Treasurer), Surgery; EDWARD MURPHY, M. D., Chemistry and Toxicology; CHARLES KNAPP, M. D. (Secretary), Principles and Practice of Medicine, and Lecturer on the Eye and Ear; T. W. STONE, M. D., Materia Medica and Therapeutics; J. E. OWEN, M. D., Anatomy; CHARLES ALEXANDER, M. D., Physiology, and Demonstrator of Anatomy; A. M. HAYDEN, M. D., Surgical Diseases of the Genito-urinary System, and Clinical Medicine; W. D. NEEL, M. D., Gynaecology and Diseases of Children; the Hon. C. L. WEDDING, Lecturer on Medical Jurisprudence.

The third regular course began October 1st, and will continue five months.

FEES.—Matriculation, \$5; lectures, \$40; practical anatomy, \$5; graduation, \$25.

Address G. B. Walker, M. D., Dean.

Iowa.

COLLEGE OF PHYSICIANS AND SURGEONS,

KEOKUK.

FACULTY (according to last year's announcement).—J. C. HUGHES, M. D. (Dean), Institutes and Practice of Surgery and Surgical Clinics; JOHN NORTH, M. D., Ph. C., Chemistry, Toxicology, and Materia Medica; GEORGE F. JENKINS, M. D., Principles and Practice of Medicine and Medical Clinics; J. A. SCROGGS, M. D., Obstetrics and Diseases of Women; GEORGE M. KELLOGG, M. D., Anatomy and Demonstrator of Anatomy; A. G. FIELD, M. D., Physiology, Pathology, General Therapeutics, and Public Hygiene; H. B. YOUNG, M. D., Lecturer on Ophthalmology and Otology; M. R. KING, Lecturer on Medical Jurisprudence; R. HEISER, Taxidermist and Curator.

FEES.—For the course, \$20; matriculation, \$5; demonstrator's ticket, \$5; graduation, \$30.

Further information can be obtained from J. C. Hughes, M. D., Dean, Keokuk, Iowa.

MEDICAL DEPARTMENT OF THE STATE UNIVERSITY OF IOWA,

IOWA CITY.

The fifteenth annual course of lectures will begin October 8, 1884, and close March 4, 1885.

A preliminary examination will be required of all students entering the first year, and also of those from other colleges which require no preliminary examination.

FACULTY.—GUSTAVUS HINRICHS, M. D., Chemistry and Toxicology; W. F. PECK, M. D. (Dean), Surgery and Clinical Surgery; P. J. FARNSWORTH, M. D., Materia Medica and Diseases of Children; W. S. ROBERTSON, M. D., Theory and Practice of Medicine, and Clinical Medicine; J. C. SHRAEDER, M. D., Obstetrics and Diseases of Women; W. D. MIDDLETON, M. D., Physiology and Microscopic Anatomy; ELMER F. CLAPP, M. D., Anatomy; O. P. SHIRAS, LL. D., Lecturer on Medical Jurisprudence; C. M. HOBBY, M. D., Lecturer on Ophthalmology and Otology; R. W. HILL, M. D., Demonstrator of Anatomy, and Curator of the Museum; O. T. GILLET, M. D. (Secretary), Assistant in Surgery; S. S. LYTLE, M. D., Prosector in Anatomy; W. D. MIDDLETON, M. D., Lecturer on Insanity.

FEES.—Lectures, \$20; matriculation, \$5; demonstrator's ticket, \$10; examination fee (for final examination), \$25; hospital ticket, \$3.

Both men and women are admitted as students.

For further information address O. T. Gillett, M. D., Secretary, Iowa City, Iowa.

THE IOWA COLLEGE OF PHYSICIANS AND SURGEONS,

DES MOINES.

FACULTY.—J. A. BLANCHARD, M. D. (Dean), Principles and Practice of Medicine; A. C. SIMONTON, M. D., Principles and Practice of Surgery, and Clinical Surgery; J. F. KENNEDY, M. D. (Secretary), Obstetrics and Clinical Diseases of Children; LEWIS SCHOOLER, M. D., Anatomy, General and Descriptive; L. C. SWIFT, M. D., Physiology, Clinical Pathology, and Hygiene; W. W. HALE, M. D., Materia Medica and Therapeutics; R. STEPHENSON, M. D., Gynecology; THOMAS SHEARER, A. M., Chemistry and Toxicology; ROBERT MCNUTT, A. M., M. D., Dermatology and Clinical Medicine; E. H. HAZEN, M. D., Diseases of the Eye and Ear; F. E. CRUTTENDEN, M. D., Diseases of the Throat and Nasal Passages; JAMES T. PRIESTLEY, M. D., Clinical Surgery and Genito-urinary Diseases; D. S. FAIRCHILD, M. D., Pathology, Histology, and Diseases of the Nervous System; the Hon. JOHN MITCHELL, Medical Jurisprudence; R. STEPHENSON, M. D., Demonstrator of Anatomy; THOMAS A. COSKERY, M. D., Assistant Demonstrator.

The third annual session began September 24, 1884, and will close March 5, 1885.

FEES.—Matriculation (paid but once), \$5; course of lectures, \$40; demonstrator's ticket, \$5; final examination fee, \$25; material for dissection, at cost.

For further information address J. A. Blanchard, M. D., Dean, 410 Fourth Street, Des Moines, Iowa.

Kentucky.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF LOUISVILLE.

LOUISVILLE.

FACULTY.—J. M. BODINE, M. D. (Dean), Anatomy and Diseases of the Ear and Throat; J. W. HOLLAND, M. D., Principles and Practice of Medicine and Clinical Medicine; E. R. PALMER, M. D., Physiology and Diseases of the Chest; T. S. BELL, M. D., State Medicine and Sanitary Science; TURNER ANDERSON, M. D., Materia Medica, Therapeutics, and Clinical Medicine; DAVID W. YANDELL, M. D., Surgery and Clinical Surgery; W. O. ROBERTS, M. D., Surgical Pathology and Operative Surgery; JOHN A. OSTERLONY, M. D., Obstetrics and Diseases of Women and Children; H. A. COTTELL, M. D., Medical Chemistry and Microscopy; W. CHEATHAM, M. D., Clinical Lecturer on Diseases of Eye, Ear, and Throat; R. B. GILBERT, M. D., Demonstrator of Anatomy; C. SKINNER, M. D., Assistant Demonstrator.

SPECIAL DEMONSTRATORS.—H. A. COTTELL, M. D., Microscopy; W. CHEATHAM, M. D., Ophthalmoscopy, Laryngoscopy, and Otoscopy; SAMUEL AYERS, M. D., Surgical Dressings.

The forty-eighth annual session began September 8th, and will continue until March 3, 1885.

FEES.—Course of lectures, \$75; matriculation ticket, \$5; graduation fee, \$30; dissecting-room, \$10; hospital ticket (required by the city), \$5.

Further information may be obtained by addressing J. M. Bodine, M. D., Dean, Louisville, Ky.

KENTUCKY SCHOOL OF MEDICINE,

LOUISVILLE.

FACULTY.—W. H. WATHEN, M. D. (Dean), Obstetrics and Diseases of Women; J. B. MARVIN, M. D., Principles and Practice of Medicine and Clinical Medicine; M. F. COOMES, M. D., Physiology and Diseases of the Eye, Ear, Throat, and Nose; C. W. KELLY, M. D. (Treasurer), Anatomy and Clinical Medicine; HENRY ORENDORF, M. D., Materia Medica, Therapeutics, and Venereal Diseases; S. E. WOODY, M. D., Medical and Public Hygiene and Clinical Lecturer on Diseases of Children; JOSEPH M. MATHEWS, M. D., Surgical Pathology and Diseases of the Rectum; J. M. HOLLOWAY, M. D., Surgery and Clinical Surgery; H. HORACE GRANT, M. D., Lecturer on Operative and Minor Surgery; R. L. THOMSON, M. D., Demonstrator of Anatomy; HON. A. BARNETT and HON. J. P. HELM, Lecturers on Medical Jurisprudence.

A good English education is necessary to admission.

The preliminary course will begin January 20, 1885. The twenty-ninth annual course will begin February 10, 1885, and will continue twenty weeks.

FEES.—Matriculation, \$5; professors' tickets, \$75; dissection, \$10; graduation, \$30; clinical lectures at the City Hospital, \$5.

Address W. H. Wathen, M. D., Dean, Fourth and Chestnut Streets, Louisville, Ky.

LOUISVILLE MEDICAL COLLEGE,

LOUISVILLE.

FACULTY.—C. W. KELLY, M. D. (Registrar), Descriptive and Surgical Anatomy and Clinical Medicine; J. A. IRELAND, M. D. (Dean), Obstetrics and Gynecology; L. D. KASTENBINE, M. D., Chemistry and Urinology; EDWARD MILLER, M. D. (Secretary), Principles and Practice of Surgery; W. H. GALT, M. D., Principles and Practice of Medicine; JAMES M. HOLLOWAY, M. D., Clinical and Operative Surgery; SAMUEL COCHRANE, M. D., Physiology; GEORGE M. WARNER, M. D., Materia Medica and Therapeutics; H. B. RITTER, M. D., Obstetrics and Gynecology (Adjunct); S. COCHRAN, M. D., Demonstrator of Anatomy; HON. W. B. FLEMING, Medical Jurisprudence.

A preliminary course began September 1st. The regular session commenced October 1st, and will terminate in the last week in February, 1885.

FEES.—Matriculation, \$5; professors' tickets, \$75; demonstrator's ticket, \$10; graduation, \$30; clinical lectures at the Louisville City Hospital, \$5.

Address Professor C. W. Kelly, Registrar, southeast corner Second and Green Streets, Louisville, Ky.

Louisiana.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF LOUISIANA,

NEW ORLEANS.

FACULTY.—T. G. RICHARDSON, M. D. (Dean), General and Clinical Surgery; SAMUEL M. BEMISS, M. D., Theory and Practice of Medicine and Clinical Medicine; STANFORD E. CHAILLÉ, M. D., Physiology and Pathological Anatomy; JOSEPH JONES, M. D., Chemistry and Clinical Medicine; SAMUEL LOGAN, M. D., Anatomy and Clinical Surgery; ERNEST S. LEWIS, M. D., Obstetrics and Diseases of Women and Children; JOHN B. ELLIOTT, M. D., Materia Medica, Therapeutics, and Hygiene; S. D. KENNEDY, M. D., Lecturer on Diseases of the Eye and Ear; ALBERT B. MILES, M. D., Demonstrator of Anatomy.

The fifty-first annual course will begin October 20, 1884, and close March 27, 1885. The Charity Hospital furnishes material for clinical and operative medicine and surgery.

FEES.—Tickets of the professors, \$140; practical anatomy, \$10; matriculation, \$5; graduation, \$30.

For further information address T. G. Richardson, M. D., Dean, New Orleans, La.

Maine.

MEDICAL SCHOOL OF MAINE

(BOWDOIN COLLEGE, BRUNSWICK).

In the absence of an announcement, we print the following:

FACULTY.—ISRAEL T. DANA, M. D., Pathology and Practice; ALFRED MITCHELL, M. D. (Secretary), Obstetrics and Diseases of Women and Children; CHARLES W. GODDARD, Medical Jurisprudence; FREDERIC H. GERRISH, M. D., Anatomy; HENRY CARMICHAEL, Ph. D., Chemistry; BURT G. WILDER, M. D., Physiology; STEPHEN H. WEEKS, M. D., Surgery and Clinical Surgery; CHARLES O. HUNT, M. D., Materia Medica and Therapeutics; IRVING E. KIMBALL, M. D., Demonstrator of Anatomy; EVERETT T. NEALEY, M. D., Demonstrator of Histology.

Candidates for matriculation are examined unless they are graduates of a literary institution.

FEES.—Lectures, \$78; matriculation (each term), \$5; graduation, \$25; analytical chemistry, \$10.

For further information address Alfred Mitchell, M. D., Secretary, Brunswick, Me.

Maryland.

UNIVERSITY OF MARYLAND, SCHOOL OF MEDICINE,

BALTIMORE.

The chair of chemistry is vacant, and we understand that it will not be filled this year. The lectures in that branch will be given by R. Dorsey Coale, Ph. D.

FACULTY.—WILLIAM E. A. AIKIN, M. D., LL. D., Chemistry and Pharmacy (emeritus); G. W. MILTENBERGER, M. D., Obstetrics; RICHARD MCSHERRY, M. D., Principles and Practice of Medicine; CHRISTOPHER JOHNSTON, M. D.,

Surgery (emeritus); SAMUEL C. CHEW, M. D., *Materia Medica* and Therapeutics, and Lecturer on Diseases of the Throat and Chest; FRANK DONALDSON, M. D., (Clinical) Diseases of the Throat and Chest; WILLIAM T. HOWARD, M. D., Diseases of Women and Children and Clinical Medicine; JULIAN J. CHISHOLM, M. D., Eye and Ear Diseases; FRANCIS T. MILES, M. D., Physiology and (Clinical) Diseases of the Nervous System; L. McLANE TIFFANY, M. D. (Dean), surgery; J. EDWIN MICHAEL, M. D., Anatomy and Clinical Surgery; I. EDMONDSON ATKINSON, M. D., Pathology and (Clinical) Dermatology; R. D. COALE, Ph. D., Chemistry and Toxicology; F. J. S. GORGAS, M. D., Principles of Dental Science, Dental Surgery, and Dental Mechanism; J. H. HARRIS, M. D., Operative and Clinical Dentistry; RANDOLPH WINSLOW, M. D., Demonstrator of Anatomy; HERBERT HARLAN, M. D., Assistant Demonstrator; J. LEIGHT DÖRKSEN, M. D., H. P. GALLAGHER, M. D., W. B. CANFIELD, Jr., M. D., Prosectors.

The seventy-eighth annual session began October 1st.

FEES.—Matriculation, \$5; dissection, \$10; course of lectures, \$120; graduation, \$30. Holders of scholarships pay only \$50 for the lecture course.

For further information, address Professor L. McLane Tiffany, Dean, 137 Park Avenue, Baltimore.

COLLEGE OF PHYSICIANS AND SURGEONS,

BALTIMORE.

FACULTY.—THOMAS OPIE, M. D. (Dean), Obstetrics; JOHN S. LYNCH, M. D., Principles and Practice of Medicine and (Clinical) Chest and Throat; T. S. LATIMER, M. D., Physiology and Diseases of Children; A. F. ERICH, M. D., Diseases of Women; A. FRIEDENWALD, M. D., Diseases of the Eye and Ear; C. F. BERAN, M. D., Anatomy, Genito-urinary and Orthopedic Surgery; O. J. COSKERY, M. D., Surgery; A. B. ARNOLD, M. D. (Clinical) Medicine and Diseases of the Nervous System; R. GUNDRY, M. D., *Materia Medica*, Therapeutics, and Mental Diseases; W. SIMON, M. D., Ph. D., Chemistry.

The regular winter session began October 1, 1884, and will continue until March 15, 1885.

For further information address Thomas Opie, M. D., Dean, 179 North Howard Street, Baltimore.

WOMAN'S MEDICAL COLLEGE,

BALTIMORE.

FACULTY.—B. B. BROWNE, M. D., Diseases of Women; F. A. ASHBY, M. D., Obstetrics; R. WINSLOW, M. D., Surgery; E. F. CORDELL, M. D., Principles and Practice of Medicine; W. D. BOOKER, M. D. (Dean), Physiology and Lecturer on Diseases of Children; R. H. THOMAS, M. D. (Secretary), Diseases of the Throat and Chest; J. G. JAY, M. D. (Treasurer), Anatomy and Operative Surgery; R. MURDOCK, M. D., Diseases of the Eye and Ear; C. PIGGOT, M. D., Lecturer on Chemistry; AMANDA TAYLOR NORRIS, M. D., Lecturer on *Materia Medica* and Therapeutics.

The third regular session began October 1, 1884, and will continue until May 1, 1885.

FEES.—Tickets, \$75; matriculation, \$5 (yearly); anatomy, \$10; graduation, \$30.

Address W. D. Booker, M. D. (Dean), 157 Park Avenue, Baltimore.

Massachusetts.

HARVARD MEDICAL SCHOOL

(MEDICAL DEPARTMENT OF HARVARD UNIVERSITY),

BOSTON.

As we have before announced, Dr. Oliver Wendell Holmes has resigned the chair of anatomy, becoming professor emeritus, and Dr. Calvin Ellis has resigned the office of dean. The teaching corps now stands as follows:

FACULTY.—ROBERT T. EDES, M. D., Clinical Medicine; OLIVER W. HOLMES, M. D., LL. D., Anatomy (emeritus); HENRY J. BIGELOW, M. D., Surgery (emeritus); FRANCIS MINOT, M. D., Theory and Practice of Physic; JOHN P. REYNOLDS, M. D., Obstetrics; HENRY W. WILLIAMS, M. D., Ophthalmology; DAVID W. CHEEVER, M. D., Surgery; JAMES C. WHITE, M. D., Dermatology; HENRY P. BOWDITCH, M. D. (Dean), Physiology; CHARLES F. FOLSOM, M. D., Assistant Professor of Mental Diseases; FREDERICK I. KNIGHT, M. D., Assistant Professor of Laryngology; CHARLES B. PORTER, M. D., Assistant Professor in Surgery; J. COLLINS WARREN, M. D., Assistant Professor in Surgery; REGINALD H. FITZ, M. D., Pathological Anatomy; WILLIAM L. RICHARDSON, M. D., Assistant Professor of Obstetrics; F. W. DEAPER, M. D., Assistant Professor of Legal Medicine; E. N. WHITTIER, M. D., Assistant Professor of Clinical Medicine; THOMAS DWIGHT, M. D., Anatomy; EDWARD S. WOOD, M. D., Chemistry; WILLIAM H. BAKER, M. D., Assistant Professor of Gynecology; WILLIAM B. HILLS, M. D., Assistant Professor in Chemistry; WILLIAM F. WHITNEY, M. D., Curator; M. H. RICHARDSON, M. D., Demonstrator of Anatomy, and Assistant in Surgery.

OTHER INSTRUCTORS.—S. H. DURGIN, M. D., Hygiene; HENRY P. QUINCY, M. D., Histology; F. C. SHATTUCK, M. D., Theory and Practice of Physic; FRANCIS A. HARRIS, M. D., Demonstrator of Medico-legal Examinations; F. H. WILLIAMS, M. D., *Materia Medica*; EDWARD H. BRADFORD, M. D., Clinical Surgery; FRANCIS H. DAVENPORT, M. D., Gynecology; GEORGE M. GARLAND, M. D., Clinical Medicine; JOSEPH W. WARREN, M. D., Physiology; G. W. WEST, M. D., Bandaging and Apparatus; WILLIAM W. GANNET, M. D., Pathological Anatomy; CHARLES S. MINOT, S. D., Embryology; WILLIAM C. EMERSON, M. D., Chemistry; WALTER J. OTIS, M. D., SAMUEL J. MIXTER, M. D., Anatomy; CHARLES HARRINGTON, M. D., Chemistry.

SPECIAL CLINICAL INSTRUCTORS.—JOHN HOMANS, M. D., Diagnosis and Treatment of Ovarian Tumors; FRANCIS B. GREENOUGH, M. D., and ABNER POST, M. D., Syphilis; OLIVER F. WADSWORTH, M. D., Ophthalmoscopy; J. ORNE GREEN, M. D., and CLARENCE J. BLAKE, M. D., Otology; E. G. CUTLER, M. D., and W. W. GANNET, M. D., Auscultation; JOSEPH P. OLIVER, M. D., and THOMAS M. ROTCH, M. D., Diseases of Children; SAMUEL G. WEBBER, M. D.,

and JAMES J. PUTNAM, M. D., Diseases of the Nervous System; JAMES R. CHADWICK, M. D., Gynecology.

The one hundred and second annual session began September 25, 1884, and ends on the last Wednesday in June, 1885, the intervening period being divided into two equal terms.

Except those who have passed the examination for admission to Harvard College, students will not be admitted until they have passed an examination in English, Latin, physics, and either French, German, algebra, plane geometry, or botany.

There is an optional four years' graded course; the three years' course is obligatory.

REQUIREMENTS FOR GRADUATION.—Students are examined at the end of each year's study, mainly in writing. The degree is still granted after three years' study, but the course of four years, with an average of seventy-five per cent. in all the examinations, entitles the candidate to the degree *cum laude*.

FEES.—Matriculation, \$5; each year's instruction, \$200; half-year, \$120; graduation, \$30. A few scholarships have been established.

For further particulars address Dr. H. P. Bowditch, Dean.

COLLEGE OF PHYSICIANS AND SURGEONS,

BOSTON.

FACULTY.—T. HAVEN DEARING, M. D. (Dean), Principles and Practice of Surgery; ELISHA CHENERY, M. D., Principles and Practice of Medicine; ASA F. PATTEE, M. D., Materia Medica and Therapeutics; ARTHUR H. WILSON, M. D., Anatomy; J. C. GLEASON, M. D., Clinical Medicine; H. W. DUDLEY, M. D., Pathology; GEORGE E. MECUEN, M. D., Obstetrics; ARTHUR B. MORONG, M. D., Physiology and Hygiene; WILLIAM R. CHIPMAN, M. D., Operative Surgery.

LECTURERS ON SPECIAL SUBJECTS.—Judge E. C. BUMPUS, Medical Jurisprudence; ASA F. PATTEE, M. D., Diseases of the Nervous System; J. R. BARSS, M. D., Ophthalmology and Otology; T. HAVEN DEARING, M. D., Dermatology; ARTHUR H. WILSON, M. D., Diseases of the Genito-urinary System; JOHN F. WELCH, M. D., Laryngoscopy and Diseases of the Throat; ELISHA CHENERY, M. D., Gynecology and Diseases of Children; J. C. FRASER, M. D., Orthopædic Surgery; J. W. KLINGHAMMER, M. D., Medical, C. A. PITKIN, M. D., General Chemistry; J. W. JOHNSON, M. D., Materia Medica and Therapeutics; CHARLES F. OSMAN, M. D., Obstetrics; ANDREW F. MEANS, Practice of Medicine; W. H. FALES, M. D., Demonstrator of Anatomy.

The fifth annual course will begin October 8, 1884, and end the second Wednesday in May, 1885.

FEES.—Matriculation, \$5; tickets for the full course, \$85; demonstrator's ticket, \$5; anatomical material, for each part, \$2 or \$4. Graduation fee, \$30.

For further information address T. Haven Dearing, M.D., Dean, Braintree, Mass.

Michigan.

MICHIGAN COLLEGE OF MEDICINE,

DETROIT.

FACULTY.—HENRY F. LYSTER, M. D. (President), Principles and Practice of Medicine; WILLIAM BRODIE, M. D., Clinical Medicine; JAMES B. BOOK, M. D. (Registrar), Principles and Practice of Surgery and Clinical Surgery; WILLIAM C. GUSTIN, M. D., Obstetrics, Clinical Midwifery, and Diseases of Children; DANIEL LA FERTE, M. D. (Secretary), Anatomy, Orthopædic Surgery, and Clinical Surgery; C. HENRI LEONARD, M. D., Diseases of Women and Clinical Gynecology; CHARLES DOUGLAS, M. D., Diseases of Children and Clinical Medicine; J. E. CLARK, M. D., General Chemistry and Physics; CHARLES C. YEMANS, M. D., Genito-urinary Diseases, and Diseases of the Skin; CHARLES J. LUNDY, M. D., Diseases of the Eye, Ear, and Throat; WILLIAM C. MAYBURY, Esq., Medical Jurisprudence; C. A. DEVENDORF, M. D., Clinical Obstetrics, and the Puerperal Diseases; H. C. WYMAN, M. D., Physiology and Histology; DUNCAN MCLEOD, M. D., Materia Medica and Therapeutics; A. B. CHAPIN, M. D., Principles of Medicine; F. P. ANDERSON, M. D., Lecturer on Diseases of the Nervous System; F. W. OWEN, M. D., and W. N. MEREDITH, M. D., Demonstrators of Anatomy; E. A. P. RIKY, M. D., Instructor in Microscopy.

The fifth annual session began September 2, 1884, and will continue six months. There is a three years' graded course. Students who are not in possession of the degree of a college or university, or of a certificate from a high school or other recognized educational institution, will be required to pass a satisfactory examination for admission. Students who have been admitted to other medical colleges, whose standard of matriculation is recognized by this college, will be matriculated without examination.

The requirements for graduation are as usual.

FEES.—Matriculation, \$5; regular session, \$50; preliminary (optional) term, \$5; graduation, \$20. Chemical and anatomical material "at reasonable rates."

Address James B. Book, M. D., Registrar, 303 Jefferson Avenue, Detroit, Mich.

Minnesota.

MINNESOTA COLLEGE HOSPITAL,

MINNEAPOLIS.

FACULTY.—F. A. DUNSMOOR, M. D. (Dean), Surgery; G. F. FRENCH, M. D., Obstetrics; A. W. ABBOTT, M. D., Anatomy; A. J. STONE, M. D., Diseases of Women; JOHN FULTON, Ph. D., M. D., Diseases of the Eye and Ear; T. F. QUINBY, M. D., Materia Medica and Therapeutics; JAY OWENS, M. D., Theory and Practice of Medicine; C. L. WELLS, M. D., Diseases of Children; C. H. HUNTER, M. D., Histology and Pathology; E. A. PATTON, M. D., Physiology; H. J. BURWASH, M. D., Clinical Medicine and Hygiene; W. S. LATON, M. D., Toxicology; CHARLES W. DREW, Ph. B., M. D., Chemistry; C. E. RIGGS, M. D., Nervous Diseases; JAMES QUINN, M. D., Genito-urinary Diseases; S. S. WENTWORTH, M. D., Dermatology; M. M. FRISSELL,

M. D., D. D. S., Medical and Surgical Dentistry; W. F. GRINDINGS, D. D. S., F. H. BRAUMER, D. D. S., Prosthetic Dentistry and Metallurgy; A. B. CATES, M. D. (Adjunct), Obstetrics; the Hon. EUGENE M. WILSON, Medical Jurisprudence; FRANK BURTON, M. D., Demonstrator of Anatomy.

The fourth regular session will begin October 6, 1884, and will close February 28, 1885.

Candidates having a degree in arts or sciences, or presenting a certificate from a high school or other institution in good standing, or a teacher's certificate, will be admitted without examination.

REQUIREMENTS FOR GRADUATION.—Every candidate must have dissected each part of the cadaver, in addition to the ordinary requirements.

FEES.—Matriculation, \$5; for all tickets and necessary dissecting material, \$55.

For further information address F. A. Dunsmoor, M. D., Dean, 8 Washington Avenue, South, Minneapolis, Minn.

MISSOURI.

MISSOURI MEDICAL COLLEGE,

ST. LOUIS.

THE secretary informs us that a practical chemical laboratory and a practical course in microscopy have been added, and that the graduation fee has been abolished and a fee for examination instituted in its stead.

FACULTY.—WILLIAM M. MCPHEETERS, M. D., Professor of Materia Medica and Therapeutics (emeritus); JOHN S. MOORE, M. D., Principles of Medicine and Hygiene; G. M. B. MAUGHS, M. D., Obstetrics and Diseases of Women; P. GERVAIS ROBINSON, M. D., Practice of Medicine and Clinical Medicine; J. K. BAUDY, M. D., LL. D., Psychological Medicine, Diseases of the Nervous System, Clinical Medicine, and Medical Jurisprudence; CHARLES E. MICHEL, M. D., Ophthalmology, Histology, and Pathological Anatomy; H. TUHOLSKE, M. D., Clinical Surgery and Surgical Pathology; OTTO A. WALL, M. D., Ph. G., Materia Medica, Therapeutics, and Pharmacy; C. A. TODD, A. M., M. D., Anatomy and Diseases of the Ear and Throat; J. P. KINGSLEY, M. D. (Secretary), Physiology and (Clinical) Diseases of Children; T. F. PREWITT, M. D. (Dean), Principles and Practice of Surgery and Clinical Surgery; C. O. CURTMAN, M. D., Chemistry; P. V. SCHENCK, M. D., Clinical Lecturer on Gynecology; C. A. TODD, M. D., Demonstrator of Anatomy; JUSTIN STEER, M. D., Assistant Demonstrator.

ASSISTANTS.—JUSTIN STEER, M. D.; F. D. MOONEY, M. D.

The forty-fourth annual session began October 1st and will continue five months.

REQUIREMENTS FOR GRADUATION.—Besides the ordinary requirements, the candidate must have attended the dissections and clinics in this school as long as he was a student thereof.

A preliminary examination will be held in accordance with the rules of the State boards.

FEES.—Course of lectures, \$60; matriculation (good until the following March), \$5; dissecting-room, \$10; examination for degree (not returnable), \$30.

For further information address T. F. Prewitt, M. D., Dean, 3718 N. Ninth Street, St. Louis, Mo.

ST. LOUIS MEDICAL COLLEGE,

ST. LOUIS.

FACULTY.—A. LITTON, M. D., Chemistry and Pharmacy; J. B. JOHNSON, M. D., Principles and Practice of Medicine; E. H. GREGORY, M. D., Principles and Practice of Surgery and Clinical Surgery; J. S. B. ALLEYNE, M. D. (Dean), Therapeutics and Materia Medica, and Diseases of Children; E. F. SMITH, M. D., Clinical Medicine and Pathological Anatomy; L. CH. BOISLINIERE, M. D., Obstetrics; G. BAUMGARTEN, M. D., Physiology; H. H. MUDD, M. D., Anatomy and Clinical Surgery; W. E. FISCHER, M. D., Hygiene and Forensic Medicine; R. LUEDEKING, M. D., Pathological Anatomy.

LECTURERS.—JOHN GREEN, M. D., Ophthalmology; W. L. BARRET, M. D., Diseases of Women; J. M. SCOTT, M. D., Clinical Medicine; G. A. MOSES, M. D., Clinical Gynecology; N. B. CARSON, M. D., Assistant to the Chair of Surgery; W. C. GLASGOW, M. D., Diseases of the Chest and Laryngology; J. FRIEDMAN, M. D., Demonstrator of Chemistry; EDWARD EVERS, M. D., Histology; JOHN P. BRYSON, M. D., Diseases of the Genito-urinary Organs; W. A. McCANDLESS, M. D., FRANK R. FRY, M. D., Demonstrators of Anatomy; C. H. HUGHES, M. D., Nervous Diseases; HARRY HODGEN, M. D., Curator of the Museum; E. M. NELSON, M. D., Assistant to the Chair of Obstetrics.

The forty-third annual session began September 22, 1884, and continues until March 1, 1885. All matriculates are required to pass an examination.

REQUIREMENTS FOR GRADUATION.—Three regular courses of lectures must have been attended.

FEES.—Matriculation fee (paid but once), \$5; fees for each regular term, \$90. Graduates of this institution have perpetual free admission. Graduates of any accredited regular school of medicine will be charged a fee of \$25 for attendance during a winter session.

For further information address J. S. B. Alleyne, M. D., Dean, 3132 Washington Avenue, St. Louis, Mo.

ST. LOUIS COLLEGE OF PHYSICIANS AND SURGEONS,

ST. LOUIS.

FACULTY.—LOUIS BAUER, M. D., M. R. C. S. Eng. (Dean), Principles and Practice of Surgery, Clinical Surgery, and Orthopaedic Surgery; W. B. HAZARD, M. D. (Secretary), Chemistry and Toxicology, and Nervous and Mental Diseases; ALGERNON S. BARNES, M. D., Obstetrics and Diseases of Women; J. G. LODGE, Esq., and the Hon. H. D. LAUGHLIN, Medical Jurisprudence; A. H. OHMANN-DUMESNIL, M. D., Dermatology and Syphilis; A. C. BERNAYS, M. D., Practical and Descriptive Anatomy and (temporarily) Gynecology; C. B. ELLIS, M. D., Physiology and Laryngology; E. M. POWERS, M. D., Military, Accidental, and Clinical Surgery; L. BREMER, M. D., Histology and Pathological Anatomy; W. H. MAYFIELD, M. D., Materia Medica, Thera-

peutics, Public Hygiene, and Sanitation; J. WISE, M. D., Diseases of Children; C. BARCK, M. D., Ophthalmology and Otology; A. KLEINECKE, M. D., Gynecology and Nervous and Mental Diseases (Adjunct); HENRY SUMMA, M. D., Surgery (Adjunct); C. B. ELLIS, M. D., Demonstrator of Anatomy.

The sixth annual course will begin October 13, 1884, and end on the first Saturday of March, 1885.

FEES.—Matriculation, \$5; lecture tickets (including demonstrators' fees), \$50; examination fee, \$25.

For further information address Professor Louis Bauer, Dean, 519 Pine Street, St. Louis.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF KANSAS CITY,

KANSAS CITY.

FACULTY.—HENRY F. HEREFORD, M. D. (President), Obstetrics and Diseases of Women; J. M. ALLEN, M. D., Principles and Practice of Medicine; JOHN W. JACKSON, M. D., Principles and Practice of Surgery; JOHN W. ELSTON, M. D. (Secretary), Materia Medica, Pharmacy, and Therapeutics; EUGENE R. LEWIS, A. B., M. D., General Descriptive and Surgical Anatomy; JOHN H. DUNCAN, A. B., M. D., Dermatology and Physiology; Hon. HENRY P. WHITE, Medical Jurisprudence; JOHN R. SNELL, M. D. (Dean), Clinical Medicine and Physical Diagnosis; JAMES P. JACKSON, M. D., Clinical and Operative Surgery; WILLIS P. KING, M. D., Gynecology; FLAVEL B. TIFFANY, M. D., Diseases of the Eye and Ear and Histology; JOSHUA MILLER, M. D., Orthopædic Surgery and Curator; CHARLES W. ADAMS, A. M., M. D. (Treasurer), Hygiene and Diseases of Children; ALBERT P. CAMPBELL, A. M., M. D., Diseases of the Throat and Chest; GEORGE W. DAVIS, M. D., Genito-urinary Diseases; JOHN T. EGGERS, M. D. (Adjunct), Anatomy and Demonstrator.

This session began the middle of September, 1884, and will continue twenty-six weeks.

For further information address John W. Elston, M. D., Secretary, 515 May Street, Kansas City, Mo.

New Hampshire.

DARTMOUTH MEDICAL COLLEGE (MEDICAL DEPARTMENT OF DARTMOUTH COLLEGE), HANOVER.

FACULTY (last year).—EDWIN J. BARTLETT, M. D., Chemistry and Pharmacy; JESSE P. BANCROFT, M. D., Mental Diseases; JOHN ORDONAU, M. D., LL. D., Medical Jurisprudence; CARLTON P. FROST, M. D. (Dean), Science and Practice of Medicine; LOUIS ELSBERG, M. D., Laryngology; EDWARD S. DUNSTER, M. D., Obstetrics; HENRY M. FIELD, M. D., Therapeutics and Materia Medica; WILLIAM W. SEELY, M. D., Ophthalmology; PHINEAS S. CONNER, M. D., Surgery; LYMAN B. HOW, M. D., Anatomy and Physiology; PAUL F. MUNDE, M. D., Gynecology; WILLIAM T. SMITH, M. D., Assistant Lecturer on Anatomy and Physiology.

The eighty-eighth annual course began July 30th, and was to continue sixteen weeks.

FEES.—Matriculation (paid annually), \$5; for the course, \$77; graduation fee (not returnable), \$25; chemicals and ordinary breakage, \$3.

For further information address Carlton P. Frost, M. D., Dean, Hanover, N. H.

New York.

COLLEGE OF PHYSICIANS AND SURGEONS (MEDICAL DEPARTMENT OF COLUMBIA COLLEGE),

IN THE CITY OF NEW YORK.

FACULTY.—JOHN C. DALTON, M. D. (President), Physiology and Hygiene (emeritus); ALONZO CLARK, M. D., LL. D., Pathology and Practical Medicine (emeritus); JOHN G. CURTIS, M. D. (Secretary), Physiology and Hygiene; THOMAS M. MARKOE, M. D., Principles of Surgery; WILLIAM DETMOLD, M. D., Clinical and Military Surgery (emeritus); T. GAILLARD THOMAS, M. D., Clinical Gynecology; JOHN T. METCALFE, M. D., Clinical Medicine (emeritus); HENRY B. SANDS, M. D., Practice of Surgery; JAMES W. McLANE, M. D., Obstetrics, Gynecology, and Diseases of Children; THOMAS T. SABINE, M. D., Anatomy; CHARLES F. CHANDLER, Ph. D., Chemistry and Medical Jurisprudence; EDWARD CURTIS, M. D., Materia Medica and Therapeutics; FRANCIS DELAFIELD, M. D., Pathology and Practical Medicine; WILLIAM H. DRAFER, M. D., Clinical Medicine.

CLINICAL PROFESSORS.—CORNELIUS R. AGNEW, M. D., Diseases of the Eye and Ear; ABRAHAM JACOBI, M. D., Diseases of Children; FESSENDEN N. OTIS, M. D., Venereal Diseases; EDWARD C. SEGUIN, M. D., Diseases of the Mind and Nervous System; GEORGE M. LEFFERTS, M. D., Laryngoscopy and Diseases of the Throat; WILLIAM S. HALSTED, M. D., Demonstrator of Anatomy; GEORGE H. FOX, M. D., Diseases of the Skin; T. MITCHELL PRUDEN, M. D., Director of the Physiological and Pathological Laboratory of the Alumni Association; ROBERT F. WEIR, M. D., Surgery; F. H. MARKOE, M. D., First Assistant Demonstrator of Anatomy; R. J. HALL, M. D., Second Assistant Demonstrator of Anatomy; GEORGE M. TUTTLE, M. D., Assistant to the Chair of Obstetrics; G. L. PEABODY, M. D., and A. B. BALD, M. D., Clinical Lecturers on Medicine.

The seventy-seventh course began on October 1, 1884, and will last until about the 1st of May, 1885.

FEES.—Matriculation, \$5; lectures, \$140; graduation, \$30; demonstrator, \$10.

Address John G. Curtis, M. D., Secretary, Twenty-third Street and Fourth Avenue.

ALBANY MEDICAL COLLEGE,

ALBANY.

FACULTY.—THOMAS HUN, M. D., LL. D. (Dean), Institutes of Medicine (emeritus); SAMUEL O. VAN DER POEL, M. D., LL. D., Pathology, Practice, and Clinical Medicine (emeritus); ALBERT VAN DERVEER, M. D., Ph. D., Surgery and Clinical Surgery; SAMUEL B. WARD, M. D., Pathology, Practice, Clinical Medicine, and Hygiene; MAURICE PERKINS, M. D., Chemical Philosophy and Organic Chemistry; JOHN M. BIGELOW, M. D., Materia Medica, Therapeutics,

Diseases of the Throat, and Clinical Laryngoscopy; LEWIS BALCH, M. D., Ph. D., Anatomy; JOHN P. GRAY, M. D., LL. D., Psychological Medicine; JAMES P. BOYD, M. D., Obstetrics and Diseases of Women and Children; WILLIS G. TUCKER, M. D., Ph. D. (Registrar), Inorganic and Analytical Chemistry and Medical Jurisprudence; WILLIAM HAILES, M. D., Histology and Pathological Anatomy; CYRUS S. MERRILL, M. D., Ophthalmology and Otolaryngology; FRANKLIN TOWNSEND, M. D., Physiology; FREDERICK C. CURTIS, M. D., Dermatology; HENRY HUN, M. D., Lecturer on Nervous Diseases; EUGENE VAN SLYKE, M. D., Demonstrator of Anatomy; S. R. MORROW, M. D., Lecturer Adjunct on Surgery; HENRY MARCH, M. D., Curator.

The fifty-fourth winter session began September 9, 1884, and will continue until March 4, 1885. There is a three years' graded course.

FEES.—Matriculation (yearly), \$5; lecture tickets, \$100; dissection, \$10; graduation, \$25; chemical laboratory (each course), \$10; laboratory course in histology (each course), \$10.

Address Willis G. Tucker, M. D., Registrar, 4 Lancaster Street, Albany, N. Y.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO,

BUFFALO.

FACULTY.—JULIUS F. MINER, M. D., Operative and Clinical Surgery (emeritus); THOMAS F. ROCHESTER, M. D., Principles and Practice of Medicine and Clinical Medicine; WILLIAM H. MASON, M. D., Physiology and Microscopy; E. V. STODDARD, M. D., Materia Medica and Hygiene; CHARLES CARY, M. D. (Secretary), Anatomy; MATTHEW D. MANN, M. D., Obstetrics and Gynecology; RUDOLPH A. WITTHAUS, M. D., Chemistry and Toxicology; ROSWELL PARK, M. D., Principles and Practice of Surgery and Clinical Surgery; JUDSON B. ANDREWS, M. D., Psychological Medicine; LUCIEN HOWE, M. D., Ophthalmology; MAHLON B. FOLWELL, M. D., Dermatology and Syphilis (Clinical); FREDERICK PETERSON, M. D., Pathology; D. W. HARRINGTON, M. D., Clinical Lecturer on Surgery; WILLIAM C. PHELPS, M. D., Demonstrator of Anatomy; ANSLEY WILCOX, LL. B., Lecturer on Medical Jurisprudence.

The fortieth annual course began September 25, 1884, and will continue twenty-two weeks.

FEES.—Matriculation (annually), \$5; tickets of all the professors, \$100; perpetual ticket, \$150; graduation, \$25.

Address Charles Cary, M. D., 305 Delaware Avenue, Buffalo, N. Y.

BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

FACULTY.—ISAAC E. TAYLOR, M. D. (President), Obstetrics and Diseases of Women and Children (emeritus); FORDYCE BARKER, M. D., LL. D., Clinical Midwifery and Diseases of Women; BENJAMIN W. MCCREADY, M. D., Materia Medica and Therapeutics (emeritus); AUSTIN FLINT, M. D., LL. D., Principles and Practice of Medicine and Clinical Medicine; FREDERIC S. DENNIS, M. D., Principles

and Practice of Surgery and Clinical Surgery; LEWIS A. SAYRE, M. D., Orthopædic Surgery and Clinical Surgery; ALEXANDER B. MOTT, M. D., Clinical and Operative Surgery; WILLIAM T. Lusk, M. D., Obstetrics and Diseases of Women and Children and Clinical Midwifery; A. A. SMITH, M. D., Materia Medica and Therapeutics and Clinical Medicine; AUSTIN FLINT, JR., M. D. (Secretary), Physiology and Physiological Anatomy; JOSEPH D. BRYANT, M. D., Anatomy and Clinical Surgery and (Associate) Orthopædic Surgery; R. OGDEN DOREMUS, M. D., LL. D., Chemistry and Toxicology; EDWARD G. JANEWAY, M. D., Pathological Anatomy and Clinical Medicine and (Associate) Principles and Practice of Medicine.

PROFESSORS OF SPECIAL DEPARTMENTS.—HENRY D. NOYES, M. D., Ophthalmology and Otolaryngology; EDWARD L. KEYES, M. D., Cutaneous and Genito-urinary Diseases; JOHN P. GRAY, M. D., LL. D., Psychological Medicine and Medical Jurisprudence; GASPAR GRISWOLD, M. D., Demonstrator of Anatomy; J. LEWIS SMITH, M. D., Clinical Professor of Diseases of Children; CHARLES A. DOREMUS, M. D., Ph. D., Professor Adjunct to the Chair of Chemistry and Toxicology; BEVERLEY ROBINSON, M. D., Clinical Professor of Medicine; FRANCKE H. BOSWORTH, M. D., Diseases of the Throat.

The twenty-fourth regular session began September 17, 1884, and extends to the latter part of March, 1885. At its close, the spring session begins, and lasts until about the middle of June.

FEES FOR THE WINTER SESSION.—Tickets, \$20 each, or all for \$140; matriculation, \$5; dissection, \$10; graduation, \$30.

Address the secretary, Professor Austin Flint, Jr., Bellevue Hospital Medical College, New York City.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

FACULTY.—ALFRED C. POST, M. D., LL. D. (President), Clinical Surgery (emeritus); CHARLES INSLEE PARDEE, M. D. (Dean), Otolaryngology; J. W. S. ARNOLD, M. D., Physiology and Histology (emeritus); JOHN C. DRAPER, M. D., LL. D., Chemistry; ALFRED L. LOOMIS, M. D., Pathology and Practice of Medicine; WILLIAM DARLING, M. D., LL. D., F. R. C. S., General and Descriptive Anatomy; WILLIAM H. THOMSON, M. D., Materia Medica and Therapeutics, and Diseases of the Nervous System; J. WILLISTON WRIGHT, M. D., Surgery; WILLIAM M. POLK, M. D., Obstetrics and Diseases of Women and Children; S. OAKLEY VAN DER POEL, M. D., LL. D., Public Hygiene; LEWIS A. STIMSON, M. D., Physiology and Histology, Clinical Surgery; STEPHEN SMITH, M. D., Clinical Surgery; A. E. MACDONALD, LL. B., M. D., Medical Jurisprudence and Diseases of the Mind; HERMAN KNAPP, M. D., Ophthalmology; FANEUIL D. WEISSE, M. D., Practical and Surgical Anatomy; R. A. WITTHAUS, M. D., Physiological Chemistry; JOSEPH E. WINTERS, M. D., Demonstrator of Anatomy.

CLINICAL PROFESSORS.—H. G. PIFFARD, M. D., Dermatology; F. R. S. DRAKE, M. D., Practice of Medicine; N. M. SHAFFER, M. D., Orthopædic Surgery; JOSEPH E. WIN-

TERS, M. D., Diseases of Children; WILLIAM C. JARVIS, M. D., Laryngology; LAURENCE JOHNSON, M. D., Medical Botany; P. A. MORROW, M. D., Venereal Diseases.

The forty-fourth session began October 1st, and lasts until the middle of March.

The fees for the winter session are the same as at the Bellevue Hospital Medical College. There is a fund for assisting a limited number of needy students, preferably the sons of physicians or clergymen, who pay \$48 for the winter session, together with the matriculation fee. There are ten scholarships.

Communications may be addressed to Professor Charles Inslee Pardee, M. D., Dean, 410 East Twenty-sixth Street.

COLLEGE OF MEDICINE,
SYRACUSE UNIVERSITY,
SYRACUSE.

FACULTY.—FREDERICK HYDE, M. D. (Dean), Principles and Practice of Surgery; HENRY D. DIDAMA, M. D., Principles and Practice of Medicine and Clinical Medicine; NELSON NIVISON, M. D., Physiology, Pathology, and Hygiene; WILFRED W. PORTER, M. D., Obstetrics and Gynecology; WILLIAM T. PLANT, M. D. (Registrar), Diseases of Children and Clinical Medicine; ROGER W. PEASE, M. D., Operative and Clinical Surgery; ALFRED MERCER, M. D. (Treasurer), Minor and Clinical Surgery; W. MANLIUS SMITH, M. D., Chemistry and Botany; JOHN VAN DUYN, M. D., Ophthalmology and Otolaryngology; M. A. KNAPP, Esq., Forensic Medicine; GAYLORD P. CLARK, M. D., Anatomy; W. H. DUNLAP, M. D., Materia Medica and Therapeutics; DAVID M. TOTMAN, M. D., Lecturer on Physiology; A. CLIFFORD MERCER, M. D., Lecturer on Microscopy and Histology; W. H. MILLS, M. D., Director of Anatomical Laboratory, and Librarian; H. L. ELSNER, M. D., Lecturer on the Practice of Medicine; J. C. HEFFRON, M. D., Lecturer on Microscopy and Histology; A. B. MILLER, M. D., Instructor in Obstetrics and Gynecology.

The first term of the thirteenth college year will begin October 7, 1884, and end the second Tuesday in February, 1885. The second term will begin the second Wednesday of February, 1885, and continue until the second Thursday of June, 1885.

FEES.—Matriculation, \$5; practical anatomy, \$10; tuition for the year, \$100; either term alone, \$65; graduation, \$25.

Address William T. Plant, M. D., Registrar, Syracuse, N. Y.

LONG ISLAND COLLEGE HOSPITAL,
BROOKLYN.

FACULTY.—DANIEL AYRES, M. D., LL. D., Surgical Pathology and Clinical Surgery (emeritus); SAMUEL G. ARMOR, M. D., LL. D. (Dean), Principles and Practice of Medicine and Clinical Medicine; GEORGE W. PLYMPTON, M. D., Physics, Chemistry, and Toxicology; CORVON L. FORD, M. D., LL. D., Anatomy; ALEXANDER J. C. SKENE, M. D., Medical and Surgical Diseases of Women and Diseases of Children;

JARVIS S. WIGHT, M. D. (Registrar), Operative and Clinical Surgery; JOSEPH H. RAYMOND, M. D., Physiology and Sanitary Science; EDWARD SEAMAN BUNKER, M. D., Histology and General Pathology; JOHN A. MCCORKLE, M. D., Materia Medica and Therapeutics; CHARLES JEWETT, M. D., Obstetrics.

LECTURERS ON SPECIAL SUBJECTS.—JONATHAN S. PROUT, M. D., Diseases of the Eye; ARTHUR MATHEWSON, M. D., Diseases of the Ear; SAMUEL SHERWELL, M. D., Diseases of the Skin; THOMAS R. FRENCH, M. D., Laryngology; HENRY N. READ, M. D., Diseases of Children; FRANCIS H. STUART, M. D., Obstetrics; ELIAS H. BARTLEY, M. D., Physiological and Practical Chemistry; GEORGE H. ATKINSON, M. D., Genito-urinary Diseases; FRANK E. WEST, M. D., Physical Diagnosis and Diseases of the Kidney; EDWIN A. LEWIS, M. D., Anatomy; JOHN C. SHAW, M. D., Diseases of the Nervous System; ———, Medical Jurisprudence; FRANK MADDEN, M. D., Demonstrator of Anatomy.

The collegiate year is divided into two terms—the preliminary and the regular term. The elementary branches are taught in the former mainly by recitations, the students being divided into three grades. At present the graded course is optional. The preliminary term began September 17, 1884, and the regular term will begin January 5, 1885.

FEES.—Yearly matriculation, \$5; preliminary term, \$40; regular term, \$100; demonstrator's ticket, \$5; graduation, \$25; practical chemistry, \$5.

For further information, address Dr. Samuel G. Armor, Dean, Mansion House, Brooklyn.

MEDICAL DEPARTMENT OF
NIAGARA UNIVERSITY,
BUFFALO.

FACULTY.—JOHN CRONYN, M. D. (President), Principles and Practice of Medicine and Clinical Medicine; CHARLES C. F. GAY, M. D., Clinical and Operative Surgery; WILLIAM S. TREMAINE, M. D., Principles and Practice of Surgery and Clinical Surgery; THOMAS LOTHROP, M. D., Obstetrics; WILLIAM H. HEATH, M. D., Descriptive and Surgical Anatomy; AUGUSTUS R. DAVIDSON, M. D., Medical Chemistry, Toxicology, and Dermatology; GEORGE E. FELL, M. D., Physiology and Microscopy; CHARLES G. STOKTON, M. D., Materia Medica and Therapeutics; CLAYTON M. DANIELS, M. D., Clinical Surgery and Adjunct Professor of Surgery; HENRY D. INGRAHAM, M. D., Gynecology and Pædiatrics; ALVIN A. HUBBELL, M. D. (Secretary), Ophthalmology, Otolaryngology, and Laryngology; HON. JOSEPH M. CONGDON, Jurisprudence; FLOYD S. CREGO, M. D., Lecturer on Nervous Diseases and Insanity; CARLTON C. FREDERICK, M. D., Lecturer on Obstetrics; DOUGALD MACNIEL, M. D., Lecturer on Dermatology; HERBERT MICKLE, M. D., Lecturer on Pathology and Pathological Anatomy; FREDERICK R. CAMPBELL, M. D., Lecturer on Hygiene; FRANK H. POTTER, M. D., Demonstrator of Surgery; JOHN L. C. CRONYN, M. D., Demonstrator of Anatomy; EDWARD CLARK, M. D., Assistant Demonstrator of Anatomy.

The regular winter term began October 1, 1884, and will

continue until March 24, 1885. The spring term will open April 1, 1885, and close May 29, 1885.

FEES.—Matriculation, \$5; winter course, \$60; spring course, \$15; anatomy, \$5; graduation, \$25.

For further particulars address A. A. Hubbell, M. D., Secretary, 212 Franklin Street, Buffalo, N. Y.

NEW YORK POLYCLINIC,

NEW YORK.

FACULTY.—JAMES R. LEAMING, M. D. (President), Diseases of the Chest and Physical Diagnosis; JOHN H. RIPLEY, M. D., Diseases of Children; E. DARWIN HUDSON, JR., M. D., General Medicine and Diseases of the Chest; LOUIS ELSEBERG, M. D., Laryngology and Rhinology; LANDON CARTER GRAY, M. D., Diseases of the Mind and Nervous System, and Electropathy; THOMAS A. MCBRIDE, M. D., Diseases of the Mind and Nervous System; RICHARD C. BRANDEIS, M. D., Laryngology, Rhinology, and Otolaryngology; A. R. ROBINSON, M. D., and EDWARD B. BRONSON, M. D., Dermatology; JOHN A. WYETH, M. D. (Secretary), and A. G. GERSTER, M. D., General and Genito-urinary Surgery; PAUL F. MUNDÉ, M. D., W. GILL WYLIE, M. D., and JAMES B. HUNTER, M. D., Gynecology; EMIL GREENING, M. D., and DAVID WEBSTER, M. D., Ophthalmology; V. P. GIBNEY, M. D., Orthopædic Surgery; WALTER R. GILLETTE, M. D., Obstetrics; GEORGE B. FOWLER, M. D., Physiological Chemistry.

INSTRUCTORS.—DONALD M. CAMMANN, M. D., and W. C. CAMPBELL, M. D., Diseases of the Chest and Physical Diagnosis; R. C. M. PAGE, M. D., and C. M. CAULDWELL, M. D., General Medicine and Diseases of the Chest; R. MILBANK, M. D., Diseases of Children; HENRY SCHWEIG, M. D., Diseases of the Throat, Nose, and Ear; GEORGE T. JACKSON, M. D., Diseases of the Skin; M. A. STARR, M. D., Diseases of the Mind and Nervous System; W. L. WARDWELL, M. D., Operative Surgery on the Cadaver; R. M. CRAMER, M. D., and R. B. KIMBALL, M. D., Minor Surgery and Surgical Dressings; CLEMENT CLEVELAND, M. D., JOSEPH D. ANWAY, M. D., E. H. GRANDIN, M. D., A. M. JACOBUS, M. D., and JAMES R. GOFFE, M. D., Gynecology; E. FRIEDENBERG, M. D., and A. BARKER, M. D., Diseases of the Eye; ROBERT A. MURRAY, M. D., Obstetrics.

The regular session of 1884-'85 opened on Monday, September 22d, and will continue until June 1, 1885. None but practitioners are admitted, and the classes are so divided that each member may have an opportunity to study the clinical features of cases with which he is brought in contact.

FEES.—Diseases of the Chest, Physical Diagnosis, and General Medicine, \$25; Diseases of Children, \$15; Diseases of the Nervous System and Electropathy, \$15; Diseases of the Throat, Nose, and Ear, \$15; General Genito-urinary and Orthopædic Surgery, Surgical Dressings, and Operations on the Cadaver (\$2 additional), \$35; Diseases of Women, \$35; Diseases of the Eye, \$15; Diseases of the Skin, \$15; Obstetrics, \$15; Physiological Chemistry, including Urinary Analysis, \$10.

For further information address John A. Wyeth, M. D., Secretary, 214 and 216 East Thirty-fourth Street, New York.

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL,

NEW YORK.

FACULTY.—JAMES L. LITTLE, M. D., Clinical and Operative Surgery; WILLIAM A. HAMMOND, M. D., Diseases of the Mind and Nervous System and Medical Electricity; D. B. ST. JOHN ROOSA, M. D., LL. D. (President), Diseases of the Eye and Ear; F. R. STURGIS, M. D., Diseases of the Skin and Genito-urinary Organs and Venereal Diseases; CLINTON WAGNER, M. D., Diseases of the Nose and Throat; T. E. SATTERTHWAITE, M. D., Pathology and General Medicine; MARY PUTNAM JACOBI, M. D., Diseases of Children; B. F. DAWSON, M. D., Diseases of Women; E. C. SPITZKA, M. D., Anatomy and Physiology of the Nervous System; M. J. ROBERTS, M. D., Orthopædic Surgery and Mechanical Therapeutics; E. L. PARTRIDGE, M. D., Obstetrics; CHARLES L. DANA, M. D., Diseases of the Mind and Nervous System and Medical Electricity; ALEXANDER J. C. SKENE, M. D., Diseases of Women; ANDREW H. SMITH, M. D., Clinical Medicine and Therapeutics; W. O. MOORE, M. D., Diseases of the Eye and Ear; W. F. FLUHRER, M. D., Clinical Surgery; AMEROSE L. RANNEY, M. D., Applied Anatomy; BACHE McE. EMMET, M. D., Diseases of Women; E. KERSHNER, M. D., Naval, Military, and State Hygiene; W. D. MCKIM, M. D., Operative Surgery.

ASSOCIATE PROFESSORS.—S. M. ROBERTS, M. D., Diseases of Children; W. H. PORTER, M. D., Pathology and Clinical Medicine; H. G. LITTLE, M. D., Genito-urinary and Venereal Diseases; C. A. VON RAMDOHR, M. D., Obstetrics.

LECTURERS.—S. D. POWELL, M. D., Surgical Dressings; S. S. BURT, M. D., Physical Diagnosis; GRAEME M. HAMMOND, M. D., Electro-Therapeutics; J. B. EMERSON, M. D., Ophthalmology; S. J. MCNUTT, M. D., Children's Diseases; N. E. BRILL, M. D., Topographical Anatomy and Development of the Nervous System; F. C. RILEY, M. D., Ophthalmology; J. H. HAWLEY, M. D., and T. KEUNE, M. D., Diseases of Women; G. R. ELLIOTT, M. D., Orthopædic Surgery and Mechanical Therapeutics.

The regular term opened October 1, 1884, and will continue until June 2, 1885. No under-graduates are admitted, but the school is open to all legalized practitioners.

FEES.—Clinical and Orthopædic Surgery and Mechanical Therapeutics, \$20; Operative Surgery, \$20; Diseases of the Nervous System and Electro-Therapeutics, \$20; Anatomy and Physiology of the Nervous System, \$20; Diseases of the Eye and Ear, \$20; Operative Surgery of the Eye, \$15; Diseases of the Nose and Throat, \$15; Pathology, Physical Diagnosis and Clinical Medicine, \$20; Urinary Analysis, \$15; Normal Histology, \$15; Pathological Histology, \$25; Diseases of Children, \$15; Clinical Gynecology, \$30; Clinical Obstetrics, \$10; Venereal and Skin Diseases, \$20; Applied Anatomy of the Nervous System, \$15; of the Eye and Ear, \$5; and of the Throat and Nose, \$5; Practical Pharmacy and Medical Chemistry, \$15; Military, Naval, and State Hygiene, \$20.

For further information address F. R. Sturgis, M. D., Secretary, 226 East Twentieth Street, New York.

Ohio.

CINCINNATI COLLEGE OF MEDICINE AND SURGERY,

CINCINNATI.

FACULTY.—R. C. STOCKTON REED, M. D., Materia Medica, Therapeutics, and State Medicine; J. B. HAIGHT, M. D., Principles and Practice of Medicine; C. A. LEE REED, M. D., Obstetrics and Gynecology; GEORGE B. ORR, M. D., Principles and Practice of Surgery and Clinical Surgery; J. H. HAZARD, M. D., Physiology; JOHN BOHLANDER, M. D., Chemistry and Toxicology; M. L. AMICK, M. D., Anatomy; W. R. AMICK, M. D., Ophthalmology and Otolaryngology; ANDERSON N. ELLIS, M. D., Laryngology; JOSEPH T. WALLINGFORD, M. D., Diseases of Children, and (Adjunct) Midwifery; W. K. BOYLAN, M. D., Materia Medica and Therapeutics; D. W. CLANCEY, M. D., D. D. S., Oral Surgery; JOHN G. REED, M. D., Demonstrator of Anatomy; W. F. TAYLOR, M. D., Dermatology, Genito-urinary and Venereal Diseases.

The fiftieth regular session began September 16, 1884, and will continue until February 28, 1885.

FEES.—General ticket, \$40; matriculation, \$5; demonstrator's ticket (including material), \$10; hospital ticket, \$5; graduation, \$25.

Address J. T. Wallingford, Secretary, 211 Baymiller Street, Cincinnati, Ohio.

MIAMI MEDICAL COLLEGE,

CINCINNATI.

FACULTY.—JOHN A. MURPHY, M. D., Clinical Medicine; E. WILLIAMS, M. D., Ophthalmology, Aural Surgery, and Clinical Ophthalmology; W. CLENDENIN, M. D. (Dean), Descriptive and Surgical Anatomy; WILLIAM H. TAYLOR, M. D. (Secretary and Treasurer), Obstetrics and Clinical Midwifery; THOMAS H. KEARNEY, M. D., Principles of Surgery and Surgical Diseases; J. C. MACKENZIE, M. D. (Registrar), Principles and Practice of Medicine; W. B. DAVIS, M. D., Materia Medica and Therapeutics; BYRON STANTON, M. D., Diseases of Women and Children, and Clinical Gynecology; WILLIAM L. DUDLEY, M. D., Chemistry and Toxicology; N. P. DANDRIDGE, M. D., Genito-urinary and Venereal Diseases; JOSEPH EICHBERG, M. D., Physiology, Clinical Laryngology, and Hygiene; F. W. LANGDON, M. D., Descriptive and Surgical Anatomy.

The twenty-fifth annual course began September 18th, and will continue five months and a half.

REQUIREMENTS FOR GRADUATION.—As usual, except that two courses at certain colleges of dentistry or pharmacy, preceding a course at this college, are accepted, and that courses in practical anatomy and practical chemistry are obligatory; also attendance at a clinical course at the City Hospital.

FEES.—Matriculation fee (annually), \$5; regular lecture term, \$75; graduation, \$25; demonstrator's ticket, \$5; practical chemistry, \$7; practical physiology and histology, \$7; single tickets, \$10; hospital ticket, \$5; special course in operative surgery, including material, \$25.

For further information address W. Clendenin, M. D., Dean, 136 West Seventh Street, Cincinnati.

Oregon.

MEDICAL DEPARTMENT OF
WILLAMETTE UNIVERSITY,

PORTLAND.

FACULTY.—D. PAYTON, M. D., Diseases of Women and Children (emeritus); L. L. ROWLAND, M. D., Physiology and Microscopy (emeritus); R. GLISAN, M. D., Obstetrics (emeritus); WILLIAM H. WATKINS, M. D., Theory and Practice of Medicine; HOLT C. WILSON, M. D., Principles and Practice of Surgery; E. P. FRASER, M. D. (Dean), Diseases of Women and Children; JAMES BROWNE, M. D., LL. D., General and Surgical Anatomy; S. E. JOSEPHI, M. D., Obstetrics and Psychological Medicine; C. H. WHEELER, M. D., Materia Medica and Therapeutics; O. S. BINSWANGER, M. D., P. C., Organic and Inorganic Chemistry; MATTHEW P. DEADY, LL. D., Medical Jurisprudence; F. B. EATON, M. D., Diseases of the Eye and Ear; ALFRED KINNEY, M. D., Genito-urinary Diseases; K. A. J. MACKENZIE, M. D., Clinical Medicine and Surgery.

The nineteenth annual course of lectures will commence November 3, 1884, and will continue twenty-two weeks. "Unless already a matriculate of the university, or a graduate of some respectable college, academy, or high school, every candidate shall be examined as to his previous education, and to his fitness for entering upon and appreciating the technical study of medicine." Women are admitted.

REQUIREMENTS FOR GRADUATION.—One course in dissection, besides the usual requirements.

FEES.—Course of lectures, \$120; matriculation, \$5; demonstrator's ticket, \$10; graduation, \$30.

For further information address Professor E. P. Fraser, Dean, Portland, Oregon.

Pennsylvania.

UNIVERSITY OF PENNSYLVANIA,

DEPARTMENT OF MEDICINE,

PHILADELPHIA.

FACULTY.—JOSEPH LEIDY, M. D., LL. D., Anatomy; HENRY H. SMITH, M. D., Surgery (emeritus); RICHARD A. F. PENROSE, M. D., LL. D., Obstetrics and Diseases of Women and Children; WILLIAM PEPPER, M. D. (Provost), Theory and Practice of Medicine and Clinical Medicine; D. HAYES AGNEW, M. D., LL. D., Surgery and Clinical Surgery; WILLIAM GOODELL, M. D., Clinical Gynecology; JAMES TYSON, M. D. (Secretary), General Pathology and Morbid Anatomy; HORATIO C. WOOD, M. D., Materia Medica, Pharmacy, and General Therapeutics; THEODORE G. WORMLEY, M. D., LL. D., Chemistry and Toxicology; JOHN ASHBURST, Jr., M. D., Clinical Surgery; HARRISON ALLEN, M. D., Physiology; W. F. NORRIS, M. D., Ophthalmology; G. STRANBRIDGE, M. D., Otolaryngology; LOUIS A. DUHRING, M. D., Dermatology.

A preliminary examination is required of all who are not matriculates of a recognized college or have not been examined by a county medical society in a manner referred to in the action of the Medical Society of the State in 1878.

Matriculates who do not furnish evidence of sufficient preliminary education are required to pass an examination in English and Physics, and to attend three graded winter courses of instruction of *seven* months each, consisting of didactic lectures, clinical lectures, and practical work in laboratories and hospitals.

The preliminary course opened September 15th. The annual winter session began October 1st.

REQUIREMENTS FOR GRADUATION.—These do not differ materially from those of the majority of schools.

FEES.—Matriculation, \$5; each annual course, \$150; dissecting material, \$1 a "part." There is no graduation fee. Six free scholarships are obtainable by competitive examination.

The school has its own hospital. Address Dr. James Tyson, Secretary, box 2838, Philadelphia.

JEFFERSON MEDICAL COLLEGE,

PHILADELPHIA.

FACULTY.—ELLERSLIE WALLACE, M. D., Obstetrics and Diseases of Women and Children (emeritus); J. M. DA COSTA, M. D., Practice of Medicine; WILLIAM H. PANCOAST, M. D., General, Descriptive, and Surgical Anatomy; ROBERTS BARTHOW, M. D., LL. D. (Dean), Materia Medica and General Therapeutics; HENRY C. CHAPMAN, M. D., Institutes of Medicine and Medical Jurisprudence; SAMUEL W. GROSS, M. D., Principles of Surgery and Clinical Surgery; JOHN H. BRINTON, M. D., Practice of Surgery and Clinical Surgery; THEOPHILUS PARVIN, M. D., LL. D., Obstetrics and Diseases of Women and Children; WILLIAM THOMSON, M. D., Ophthalmology (honorary); J. SOLIS COHEN, M. D., Laryngology (honorary).

The preliminary session began September 15th. The sixtieth course of lectures began October 1st, and ends the last of March. The spring session begins early in April, and closes in June. The college has a hospital of its own.

FEES.—Matriculation, \$5; full course of lectures, \$140; dissection, \$10; graduation, \$30.

For further information address Professor Roberts Barthow, Dean, at the college, Tenth Street, between Chestnut and Walnut Streets, Philadelphia.

PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE.

FACULTY.—THOMAS G. MORTON, M. D., Clinical, Operative, and Orthopædic Surgery; J. SOLIS COHEN, M. D., Diseases of the Throat and Chest; JOHN B. ROBERTS, M. D., Applied Anatomy and Operative Surgery; CHARLES H. BURNETT, M. D., Diseases of the Ear; CHARLES K. MILLS, M. D., Diseases of the Mind and Nervous System; HENRY LEFFMANN, M. D., Clinical Chemistry and Hygiene; ARTHUR VAN HARLINGEN, M. D., Diseases of the Skin; EDWARD L. DUEB, M. D., Obstetrics and Diseases of Women and Children; GEORGE C. HARLAN, M. D., Diseases of the Eye; J. HENRY C. SIMES, M. D., Genito-urinary and Venereal Diseases; FREDERICK P. HENRY, M. D., Pathology and Microscopy; WASHINGTON H. BAKER, M. D., Obstetrics and Diseases of Women and Children (Adjunct).

Clinical and practical instruction in the medical and surgical specialties is afforded, to physicians only, during the entire year.

In addition to the clinical facilities of the dispensary and domiciliary out-patient department of the College, the professors utilize, for purposes of instruction, their services in the Philadelphia, Pennsylvania, Wills, Howard, Episcopal, Orthopædic, Presbyterian, German, and St. Mary's Hospitals.

The fee for each branch, per session of six consecutive weeks, is \$15. Any two branches, \$25. Any number of branches may be taken. Pupils, after studying in all departments, may, by examination, become Fellows of the College.

For full announcements, address John B. Roberts, M. D., Secretary, 1118 Arch Street, or at the College Building.

Vermont.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT.

BURLINGTON.

FACULTY.—WILLIAM DARLING, M. D., F. R. C. S., General and Special Anatomy; JOHN ORDRONAU, M. D., LL. D., Medical Jurisprudence (emeritus); ALBERT FREEMAN, A. KING, M. D., Obstetrics and Diseases of Women; HENRY DWIGHT HOLTON, M. D., Materia Medica and Therapeutics; JAMES LAWRENCE LITTLE, M. D., Principles and Practice of Surgery; ASHBEEL PARMELEE GRINNELL, M. D. (Secretary), Theory and Practice of Medicine; RUDOLPH AUGUST WITTHAUS, M. D., Chemistry and Toxicology; J. HENRY JACKSON, M. D., Physiology and Microscopic Anatomy.

The regular term opens the first Thursday in March of each year, and continues seventeen weeks.

FEES.—Matriculation (each term), \$5; course of lectures, \$70; graduation, \$25. Students who have already attended two full courses of lectures in other regular schools are admitted on paying the matriculation fee and \$25. Theological students are admitted on general ticket by paying the matriculation fee.

For further information address A. P. Grinnell, M. D., Secretary, Burlington, Vt.

* * * We regret that lack of space compels us to omit a number of colleges, for which we had prepared matter based upon the lists given in our Students' Number last year, not having received from most of them announcements for 1884-'85.

NEWS ITEMS, ETC.

The New York Post-Graduate Medical School and Hospital opened its regular winter session on the 1st inst. During the summer the building occupied by the school has been improved, and much has been done to increase the facilities for teaching and to add to the comfort of the classes. Among other noteworthy additions is that of a photograph gallery for taking pictures of important cases. The lecture, operating, anatomical, and other rooms are commodious, and are fitted up with the appliances necessary for teaching the branches to which

they are devoted. The two upper floors of the building are devoted to hospital purposes.

During the session just opened the following clinics will be given: Diseases of the Eye and Ear; Nose and Throat; Skin and Venereal Diseases; Physical Diagnosis; General Medicine; Obstetrics; Gynecology; Surgery—General, Operative, and Orthopaedic, with Surgical Dressings; Urinary Analysis; Histology; Pathology; Diseases of the Nervous System, with Anatomy and Physiology of the same; Applied Anatomy and Genito-urinary Diseases.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 30, 1884:

DISEASES.	Week ending Sept. 23.		Week ending Sept. 30.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	0	0	2	0
Typhoid Fever.....	44	11	57	12
Scarlet Fever.....	17	1	25	2
Cerebro-spinal meningitis....	5	4	3	2
Measles	16	5	17	4
Diphtheria.....	33	17	28	12

The Health of Naples.—A medical gentleman has suggested to us that the present is a good time to "see Naples and die."

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 21, 1884, to September 27, 1884:*

MIDDLETON, PASMORE, Major and Surgeon. Having reported from sick leave of absence, assigned to duty at Fort Leavenworth, Kan. Par. 2, S. O. 188, Headquarters Department of the Missouri, September 19, 1884.

WHITE, R. H., Captain and Assistant Surgeon. Assigned to duty as Post Surgeon at Fort Winfield Scott, Cal., relieving Assistant Surgeon A. S. Polhemus, who, upon being relieved, will report to commanding officer at Alcatraz Island, Cal., for duty. Par. 1, S. O. 113, Headquarters Department of California, September 19, 1884.

HALL, JOHN D., Captain and Assistant Surgeon. Assigned to duty at Fort Townsend, Washington Territory, to relieve Surgeon R. S. Vickery. Surgeon Vickery, on being relieved, directed to report to commanding officer at Vancouver Barracks, Washington Territory, for duty. Par. 3, S. O. 140, Headquarters Department of the Columbia, September 15, 1884.

TESSON, L. S., Captain and Assistant Surgeon. Directed to report to commanding officer at Fort Stockton, Tex., for temporary duty. Par. 3, S. O. 127, Headquarters Department of Texas, September 22, 1884.

BIRMINGHAM, H. P., First Lieutenant and Assistant Surgeon. Leave of absence extended twenty days. Par. 2, S. O. 116, Headquarters Division of the Missouri, September 22, 1884.

MADDOX, T. J. C., First Lieutenant and Assistant Surgeon. Directed to report to commanding officer, post of San Antonio, Tex., for duty. Par. 5, S. O. 127, Headquarters Department of Texas, September 22, 1884.

BARROWS, C. C., First Lieutenant and Assistant Surgeon. Leave of absence extended one month. Par. 6, S. O. 97, Headquarters Division of the Pacific, September 19, 1884.

DIETZ, W. D., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Selden, N. M. (Post Surgeon). Par. 4, S. O. 187, Headquarters Department of the Missouri, September 18, 1884.

McCaw, W. D., First Lieutenant and Assistant Surgeon. Assigned to duty as Post Surgeon, Fort Craig, N. M. Par. 5, S. O. 187, Headquarters Division of the Missouri, September 18, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending September 27, 1884:*

BLOODGOOD, D., Medical Inspector. Ordered to Washington for examination preliminary to promotion, and as to qualifications for sea duty, October 1, 1884.

HORD, W. T., Medical Director. Detailed as member of Naval Examining Board, October 1, 1884.

TURNER, T. J., Medical Director. Detailed as member of Naval Examining Board, October 1, 1884.

BOYD, J. C., Passed Assistant Surgeon. Placed on waiting orders, September 25, 1884.

OBERLY, A. S., Surgeon. Ordered to Washington for examination preliminary to promotion, and as to qualifications for sea duty, October 1, 1884.

Society Meetings for the Coming Week:

MONDAY, October 6th: Medico-Chirurgical Society of German Physicians; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Monmouth County, N. J., Medical Society (Freehold); Union County, N. J., Medical Society (Elizabeth).

TUESDAY, October 7th: New York Neurological Society; Medical Society of the County of Broome, N. Y. (annual); Elmira, N. Y., Academy of Medicine; Medical Society of the County of Columbia, N. Y. (Hudson); Buffalo Medical Association; Medical Society of the County of Orange, N. Y. (semi-annual—Goshen); Ogdensburg, N. Y., Medical Association; Medical Association of Northern New York (annual—Malone); Medical Society of the County of Schoharie, N. Y.; Croton, N. Y., Medical and Surgical Union (quarterly—Katonah); Hudson County, N. J., Medical Society (Jersey City).

WEDNESDAY, October 8th: New York Pathological Society; The American Microscopical Society of the City of New York.

THURSDAY, October 9th: Harlem Medical Association of the City of New York; Public Health Association of New York; New York Laryngological Society; Brooklyn Pathological Society; Medical Association of the Eastern District of Brooklyn.

FRIDAY, October 10th: Yorkville Medical Association (private); Medical Society of the Town of Saugerties, N. Y. (anniversary).

Miscellaneous.

MEDICAL STUDY IN GREAT BRITAIN, FRANCE, AND GERMANY.

THE number of American medical men who go abroad for the purpose of study is at present so large, and the number who desire to know the advantages to be secured by such a trip is so rapidly increasing, that a few facts regarding medical work in Europe may be of interest to many. Each country has its own method of medical education, its own hospital system, its own peculiarities of study and work. These are as different from one another as they are from our own. The chief characteristics of the various systems must be learned in order that the student may decide intelligently under which he can secure the results desired. The information which is here offered has been collected by

the writer during the past year while studying abroad. It is such as he desired to obtain before starting, and, if it aids others, his purpose will be accomplished.

Great Britain.—Although the medical schools of Great Britain are very numerous, and are to be found in many cities of England, Scotland, and Ireland, the traveler will find that medical interest centers in London, Edinburgh, and Dublin. In these cities are found the great hospitals which afford material for practical instruction, and the most eminent teachers whose names attract large numbers of students. There is no rigid system of government control over medical education in Great Britain as there is upon the Continent; and, as a result, the schools are numerous in each city and are in constant competition. In London many of the hospitals have medical schools connected with them, and, as the number of students in each school is small, rarely exceeding two hundred, they have access to the hospital and obtain much practical information by the examination of cases. As in America, instruction in the schools is given by lectures and by clinics, but, in addition to this, the English student has an opportunity to obtain more than an abstract knowledge of disease, for every man is obliged to serve as dresser or clerk in a hospital for six months before graduation. While clerk he has access to the hospital wards for three hours daily; he takes the history of every case assigned to him, makes his examination and diagnosis, and reports both to the house physician and to the attending physician at the time of the rounds. In each division of a hospital there are about sixty beds, and from ten to fifteen clerks are in attendance, so that no man has more cases than he can work up thoroughly. When the attending physician visits the wards all the clerks accompany him, and each is questioned, more or less carefully, about his cases, interesting features of them are called to his notice, his diagnosis is discussed and corrected if necessary, and he is asked to recommend a line of treatment. The history which the clerk writes is reviewed by the house physician and then copied into the hospital records by the author. A dresser has somewhat similar duties under the direction of the house surgeon, and assists him in the application of dressings. This system requires a sacrifice of time on the part of the attending physician or surgeon, but, as he regards the instruction given in the wards as part of his duty as professor in the hospital school, it is not grudged. The benefit derived by the students by such a practical experience in the care of patients is very great. It gives him a familiarity with disease which could never be obtained from theoretical lectures or ordinary clinics.

A foreigner may obtain a position as clerk or dresser in a London hospital by appointment or by application, but not as a rule now. At some of the hospitals the professors choose their own clerks—and a personal introduction will secure a position—if the applicant is willing to await his turn. In other hospitals (St. Bartholomew's and Guy's) a dressership or clerkship may be purchased, the price being ten guineas for a three months' service, and fifteen guineas for six months. At Guy's Hospital one hundred and sixty clerks and dressers are appointed yearly, and at St. Bartholomew's and the London Hospital the number is almost as large.

The public clinics and operations at the hospitals are usually held at two in the afternoon, and to these no introduction is necessary. If a stranger wishes to visit any of the hospitals he should ascertain at what hour the rounds are made, and at that time, on presentation of his card to the attending physician or surgeon, he will be invited to accompany him through the wards. He can then see the working of the system of practical instruction just described, as well as the arrangement of the hospital, the class of cases treated, and the methods of treatment. At other times of the day the cordiality of his reception will depend largely upon the good nature of the house surgeon or physician to whom he applies, and who may be too busy to be troubled by visitors.

The term time in the English schools corresponds very nearly with that in our own, and lectures or clinics can not be attended to advantage between May and October. The summer session, lasting during May and June, is conducted largely by assistants. Hospital work, of course, continues during the entire year.

The character of instruction in English schools is very similar to that in our own, the best talent in the profession being devoted to the work of teaching. At King's College, Lister, Playfair, Ferrier, G. John-

son, and Beale; at the London Hospital College, Andrew Clark, Hutchinson, and Hughlings Jackson; at St. Thomas's Hospital, Bristowe and Croft; at the University College, Sir Henry Thompson, Heath, Barlow, Fox, and Gowers; at St. Bartholomew's, Sir James Paget and Gee—deliver lectures and hold medical or surgical clinics. Specialists are not in favor in England, and therefore special study is best conducted on the Continent; although, if the specialist has letters of introduction to English physicians, he will be shown every attention and be able to do a good deal of work in almost any department. The material in the hospitals and dispensaries in London is, of course, enormous, but it is not as available for the specialist as that in Vienna. If one desires, for example, to study diseases of the throat, he will find the clinic of Dr. Mackenzie, at the London Hospital, open twice a week, and two or three dispensary classes held for an hour every other day, whereas in Vienna he can spend six or eight hours daily in courses upon this department of medicine. And the same is true of almost every other. Sir James Paget, Sir Henry Thompson, Sir Joseph Lister, and others operate once a week before their classes. The clinics of Billroth or Albert may be attended for three hours every day. English methods of study, of teaching, of operation, are very similar to our own, as every one knows who reads the English journals; and the medical man abroad will find more that is new and suggestive on the Continent than he will in London.

The Edinburgh school attracts many students on account of the special facilities it offers for pathological work in its laboratories, and on account of its eminence in the departments of obstetrics and gynecology under the leadership of Simpson and Keith. The lectures of Grainger Stewart in general medicine and his fine clinics, and the operations of Cheyne in the surgical wards of the large hospital, contribute largely to the success of the school and to the high reputation which it has abroad as well as at home. The instruction is as practical in Edinburgh as is possible in any country where the chief end of a hospital is not the teaching of students. But, as the Edinburgh students find it to their advantage to complete their studies in Vienna, it will be better for the American to limit his stay in the former city with the view of having more time in the latter.

Few foreign physicians go at present to Dublin. The chief attractions there for many years were the obstetric out-door service in connection with the school, and the large clinic in children's diseases. There are at present in Dublin about fifteen hundred cases of confinement divided among eighty students in the course of a term. In Vienna ten thousand infants are born annually in the obstetric division of one hospital, which is accessible to any practitioner. And the number of cases of children's diseases treated at the Poliklinik in Vienna is as great as that in any dispensary in Dublin.

If a student can not afford to spend time in acquiring French or German, and desires to study in Great Britain, he will do well to pursue pathology, obstetrics, and gynecology in Edinburgh, and all other branches in London. But he will find that he will obtain very little more in these places than he could obtain in an equal time in New York. A few Americans aspire to an English degree. There are nineteen colleges in Great Britain which confer the degree of M. B., which entitles one to practice. The degree of M. D. is an honor not taken by the majority of practitioners. The Royal College of Physicians and the Royal College of Surgeons hold quarterly examinations for their degrees, which are open to American graduates who have pursued a four years' course of study. The examinations are both written, oral, and practical, the latter being conducted in the wards of one of the hospitals. The necessary qualifications may be ascertained and old examination papers may be seen at the Royal College of Physicians on Trafalgar Square, or at the Royal College of Surgeons in Lincoln's Inn Fields. A student who has taken his degree in one of the colleges of this country, and has served two years on a hospital staff, will find some difficulty in passing any of these examinations, and will be likely to estimate the value of the English diploma very much above his own.

One of the best methods of seeing and hearing the distinguished medical men in any city abroad is to attend some of the meetings of their societies. These are held weekly in the evening, in London, and admission is granted upon presentation of one's card at the door. The personal characteristics of the chief members of the profession are more

clearly seen when they are engaged in a discussion with one another than when they are lecturing to their students; and no one can fail to be interested in following an animated debate, aside from the attraction which is frequently offered by the subject under discussion. The meetings of the Pathological, the Medical, and the Medical and Chirurgical Societies are always crowded by the best men in London; and at all of them the foreigner will be sure to meet with a cordial reception if he is personally known to a member.

The hospitals and schools are so widely scattered over London, and are at such distances from each other, that no one part of the city can be suggested to the student for a place of residence. In Bloomsbury he will have no difficulty in finding apartments at a reasonable rate, and will be near the University College Hospital and the Soho Square Hospital. Guy's and St. Bartholomew's are at the East End, and lodgings near them are not desirable. In the streets off the Strand the student can find numerous boarding-houses and be within a few minutes' walk of King's College and Charing Cross Hospital. But the numerous omnibus lines make it a matter of indifference where one is located.

The cost of living in London is about the same as in New York. The best plan to pursue is to take an apartment and live in restaurants, in this way avoiding the necessity of returning from a distance to a boarding-house at meal time. Where one's own language is spoken there is little difficulty in obtaining all the necessary information after one's arrival, and the stranger needs less advice with regard to study in England than upon the continent.

France.—"Paris c'est la France" is true of medical matters as well as of all others. The chief medical college of the country, the great hospitals, the extensive and well-equipped laboratories, the enormous library and museums, the societies, the academy—are all to be found within the city limits. The most able men of France are brought together in the institutions of instruction in the capital, and to them flock students from all over the world. This is one point of contrast to the German system, under which many universities compete for favor. In Paris all the institutions are under government control, and one feature which impresses the stranger is that the national motto, "Liberté, égalité, fraternité," placed over their doors, seems to have its meaning enforced, for there is free admission to every institution, and the foreigner is welcomed everywhere and given all the advantages of the citizen. In the School of Medicine instruction is both theoretical and practical, and the true balance between the two is more nearly attained in Paris than elsewhere, the tendency in England, as in America, being to exalt theoretical lectures, and in Germany to make all teaching clinical. Specialties are not so sharply defined as in Germany, and few of the Parisian lecturers or practitioners desire to be known as specialists. The chief feature of the French school of to-day is its excellence in anatomical work, and no one can succeed in Paris unless he is a thorough anatomist. Next in prominence are the departments of surgery and neurology, and these are the favorites with students from other countries; but in all branches instruction is complete. These are, perhaps, the chief general characteristics which impress the foreigner.

The School of Medicine, situated in the Latin quarter near the crossing of the Boulevards St. Germain and St. Michel, may be taken as the medical center of Paris, and it is in this region that a student will find it convenient to live. He can obtain a furnished room in some of the many hotels in that vicinity for from 40 to 100 francs a month, according to the degree of comfort sought. His coffee and eggs will be served in his room for one franc, and he can obtain his noon breakfast (1.50 to 2.50 francs) and evening dinner (2.50 to 5 francs) in some one of the numerous good restaurants either in the Latin quarter or wherever he may find himself at meal-time. This is the best way to live in Paris as well as in London. This location is also desirable as it is central and about equally distant from the chief hospitals which most men visit, and to it many omnibus-lines converge. In the School of Medicine the theoretical lectures are given. In the school are the Musée Orfila, with its enormous collection of anatomical preparations and the great medical library, where one can find all medical books of any worth in any language as well as many of the French, German, and English periodicals. This library is open to any medical man free of charge from eleven to five and seven to ten. Near the school is the

building containing the celebrated Musée Dupuytren of pathological specimens, and in which are held the meetings of the Société de Biologie and the Anatomical Society. The École Pratique, or anatomical laboratory, is also in this vicinity. It is therefore desirable to live near the school. The medical courses open to a student are of three kinds: The didactic lectures, the laboratory work in anatomy or physiology, and the clinical courses in the hospitals. There are two terms in the schools during the year, the winter term beginning in October and lasting till March, and the summer term beginning in April and lasting till August. During the winter term the lectures are delivered by the professors, but in the summer the assistants take their places in some of the departments. Each professor lectures two or three hours a week. Each course covers a portion of the department which the professor holds, and thus it requires sometimes three or four years for him to get over his entire field. As the student is required to pursue a four years' course, he does not thereby lose any part. Among the lecturers are Sappey, Vulpian, Jaccoud, Péter, Hayem, Le Fort, Simon, and Charcot, in addition to a score of others whose names are less widely known. The lectures are accompanied by demonstrations whenever these are possible. The student will see fine dissections or difficult physiological experiments carried on with surprising facility by the aid of numerous skilled assistants while the lecturer is describing them, and operations performed on the cadaver as they are being explained. The chief feature of the lectures is their thoroughness, each subject being carefully dealt with and exhausted before it is left. Many of the lecturers attend at some large hospital, and their daily morning visit is always open to the student. In fact, students are required to follow the rounds of some professor in the hospital daily during the last two years of study, being allowed to make a selection of the professor at the beginning of each term. This enables a professor to combine practical with theoretical instruction. For example, M. Péter was lecturing in April last on diseases of the alimentary canal. Every morning at nine he made his rounds in la Charité attended by thirty or forty students, and took occasion to call their attention to any case which illustrated his lectures. This was done in a conversational manner, so that students did not hesitate to ask any questions they desired, being always sure of a considerate reply. They were then allowed to examine the patients for themselves when the patient was not too sick, under the direction of some member of the house staff. A stranger can attend any of these hospital visits as well as the didactic lectures, either joining the students as they follow the professor, or securing more special notice by the presentation of his card before the rounds begin. Some courses are wholly clinical. The professor meets his class at his hospital, and, after making his rounds, has a patient taken to an amphitheatre, and spends an hour in lecturing on his case. This method is followed by G. Sée, Vulpian, and Hardy. The art of lecturing is cultivated largely in Paris, it being a part of every examination of a student or of a candidate for a hospital or college appointment to deliver a ten minutes' lecture on a subject after ten minutes' preparation. This secures facility in giving a concise statement of a case, a quick differentiation, a definite diagnosis, and a terse outline of treatment. As every student aspires to the position of hospital externe, every externe desires to become an interne, and many internes contend for positions as assistant professors; and, as every step in the progress is made to depend on an examination in which the extemporaneous lecture plays an important part, the attention paid by both students and hospital staff to these lectures is very close, and, as a rule, all take full notes of the lecture. In surgery the lectures are supplemented by courses in operations on the cadaver, and by the surgical clinics at the hospitals. The laboratory work is probably the most perfect in Europe. Every student has to work in the dissecting-room daily during the winter semesters of the second and third year, absences being marked against him. During the first year students are obliged to do practical work in the laboratories of chemistry, physics, and natural history. And in the fourth year attendance upon operative surgical courses is also enforced. Thus practical work is made of the greatest importance. The facilities offered for it are very complete. The École Pratique, in the Rue Vauquelin, consists at present of a set of eight pavilions, each hall affording room for fifteen tables, being well ventilated and lighted. To each pavilion are assigned one prosector and three assistants, whose duty it is not

only to demonstrate to those who are dissecting, but also to deliver regular lectures. The prosector lectures three times a week, and each assistant once a week; during these lectures the students stop work and listen. The whole laboratory is under the direction of Dr. Fara-bœuf, who is present every day to direct and stimulate the work of assistants and students. He goes about from table to table asking questions of the students or suggesting points of interest, or listening to the lectures which are going on. Owing to his pleasant manner, the relation in which he stands to the students is a particularly agreeable one, and is calculated to further their interest in their work and to lead them to desire to win his commendation. The students in the dissecting-room are divided into two classes, according to their year of study, and their course in dissection is a progressive one and exceedingly minute. During the last semester over five hundred were dissecting daily. The courses on operative surgery for the fourth-year men, which are held in the same building, are also admirable. The lectures are given daily, each operation being minutely described and performed with great care on the cadaver, models, diagrams, and dissections being used to illustrate every point. Each student pays forty francs a year for the use of the laboratory, and material is furnished him free. Prizes are offered for fine dissections, and some of the most remarkable preparations in the museums have been made by students in competing for these prizes. No one can remain in Paris a month without appreciating the advantages of this careful training in anatomy. And the importance of anatomical knowledge is emphasized by making it the chief subject for examination for all degrees or positions. The physiological and pathological laboratory are no less complete in equipment, and are directed by competent "chefs de travaux," each of whom has numerous assistants. But the chief interest concentrates upon the dissecting-room. There are also laboratories for special work in each department, to which any one who desires to make special study can obtain access, and in which all appliances are furnished him for work. For the use of the hospital internes and externes of Paris there is a special laboratory, the Amphithéâtre d'Anatomie, supported by the government, where special work can be done. There are here twenty tables for dissection, and a large room for microscopic and chemical work. The numerous facilities for anatomical investigation and the avidity with which they are taken advantage of are an index of the general interest in the subject. As surgery is founded on anatomy, it is not strange that it stands second in the list of departments in which the Paris school excels. For the student the courses are very complete, and for the practitioner the opportunities for seeing operations are many and very satisfactory. The clinics of Le Fort, Gosselin, Richet, Verneuil, and Trélat are crowded with students, who have the opportunity of seeing as careful and brilliant operations as those held in any part of the globe.

The name most frequently heard in Paris is that of Charcot, and no description of the medical instruction of the city would be complete which did not include that of his course. His lectures and clinics are held at the Hôpital Salpêtrière, near the Jardin des Plantes. This is an enormous almshouse for women, with a division devoted to nervous diseases. There are in all about four thousand inmates, of whom at least six hundred are invalids. An out-door department for the treatment of nervous diseases, which is attended by Charcot, Luys, Legrande du Saulle, and others, attracts a large number of patients, from whom the wards are kept filled. Each physician attends at the out-door department one day in the week, in the morning, to examine such cases as are selected by the assistants as of peculiar interest. These consultations, as they are called, are open to practitioners, and are worth attending. The patient is brought into the office and examined, and the case is talked over in a conversational way by the attending physician and the assistants, and the diagnosis and treatment discussed. Charcot attends on Tuesday, and usually sees eight or ten cases, going over each carefully. These consultations are less formal than his clinics, and are more valuable to the practitioner, as he there has an opportunity to see the method of examination, the care in differentiation, and the fine diagnostic acumen which have made Charcot renowned. Patients come not only from all parts of Paris, but from distant cities, to these consultations, so that there is no lack of remarkable cases.

On Wednesday, Charcot makes his rounds publicly, and shows to students the interesting cases in his wards. On Friday, at 9 A. M., he gives his weekly lecture in the celebrated amphitheatre of la Salpêtrière, with its stage and rising banks of seats arranged like a theatre. This hall is darkened during the lecture, so that, by means of a brilliant calcium light, diagrams and photographs can be displayed upon the screen.

With a large material to draw from, Charcot can illustrate by cases every form of nervous disease, and, when a differentiation between apparently similar conditions is necessary, the patients can be compared and contrasted. Various stages of the same disease are shown in different patients; and, with a clearness and precision which are striking and a minuteness of detail which is characteristic, the course of the malady is illustrated from its beginning to its close. Then, by the aid of the calcium light, microscopic sections are magnified and thrown upon a screen, and the lesion in brain or cord is demonstrated, thus bringing the symptoms and pathology into a relation which is not soon forgotten. As one listens to the fluent lecturer, and notes how every portion of his subject is given its appropriate degree of importance, how the strong diagnostic points are set in relief without any sacrifice of detail, and how the entire subject is summed up in a few terse sentences at the end, one can not wonder that hundreds of hearers gather from every country to sit under his teaching, and that they come away convinced that his brilliancy is unsurpassed.

In connection with his division of the hospital, Charcot has several laboratories for physiological and pathological work, and in them there are always a number of enthusiastic young men working under his guidance. Here one can see every modern device for the examination of diseased patients, or the investigation of deceased specimens, in daily use. In the photographic department series of instantaneous pictures were being taken of patients in epileptic or hysterical convulsions. In the modeling department casts of limbs in the various forms of contracture from different causes were being made. In one room patients were tested for color-blindness, and their visual fields for various shades carefully marked on the diagrams. In another, all the electrical apparatus was collected, and patients were being treated, some by static electricity produced by an enormous Holtz machine operated by steam, some by galvanism, and others by the induced current. The hydropathic establishment is the most complete in Paris. A large museum is devoted to one of the most interesting collections of pathological specimens in Europe, and on its walls hang photographs of the patients from whom the specimens were obtained. Not the least interesting is a series of engravings of celebrated pictures in various galleries of Europe, all of which represent the miraculous cure of demoniacs, and illustrate perfectly the fact that epileptic and hysterical seizures were faithfully studied by artists in past centuries, and were accurately represented on canvas.

For completeness of equipment and for facilities for studying the pathology of nervous diseases, no laboratory in Europe can compare with that of Charcot, and, if one desires to pursue this specialty, he should not fail to spend a portion of his time under the inspiration of the great Frenchman.

Next, perhaps, to Charcot in popularity is Legrande du Saulle, whose weekly lectures on insanity attract large audiences. His clinics are supplied with patients from his division of the hospital, where idiots, epileptics, and insane are to be cared for. A visit to his school for idiots, where every known method of developing any latent faculty is employed, and where most encouraging results are obtained, should not be omitted. Permission will be readily granted by the professor, who takes such pride in the institution that he gladly shows it to any stranger who manifests an interest in the subject.

To the alienist the clinics of Professor Ball, at the Asile Ste. Anne, and the daily rounds of Dr. Magnan at the same institution, will be of interest, especially as he will there see the working of the principle of non-restraint. This asylum is one of the largest and most admirably arranged in France, and merits a visit aside from the interest of the teaching given. It is reached by an omnibus going along the Boulevard St. Michel to the Place St. Jacques.

The study of the diseases of children can be pursued in Paris to great advantage. At the Hôpital des Enfants Malades there is a daily

attendance in the out-door department of between two and three hundred children, and Simon and Bouchut hold clinics. In the hospital there are 618 beds, and every form of disease can be watched by attending the daily rounds. This hospital is in the Rue de Sèvres, No. 149, very near the Hôpital Necker, where Potain and Guyon hold their university clinics. A second large children's hospital (320 beds) is the Hôpital des Enfants Amitées, Rue d'Enfer, 74, a founding asylum where Parrot makes daily rounds and holds his clinic. Here, too, is a large out-door department. At both these hospitals one can see autopsies, if a request is made to the house physician. Their fever wards are always full, and are alone worth a visit.

Though there are numerous lying-in hospitals in Paris, the study of obstetrics can not be pursued to so great an advantage as in Vienna, it being difficult for a foreigner to obtain permission to practice in the wards, and the number of cases falling to one's lot being small.

For one who is already familiar with diseases of the skin, the Hôpital St. Louis (near the Station de l'Est) offers an enormous material for study. It has 823 beds, and a very complete hydropathic establishment. Here the clinic of Fournier on skin and syphilis is held once a week, and the rounds may be made with him every day. Besnier's lectures are also much esteemed by those who attend this hospital. In the out-door department no less than 28,000 patients are treated every year, and one can see every variety of skin disease in every stage. The time devoted to each case is necessarily limited when so many apply, and there is little opportunity to obtain any explanation of the cases. But, if one is familiar with skin diseases, the variety is an attraction. These are the chief hospitals for specialties in Paris.

The disadvantages of study in Paris are owing to the facts that the hospitals are so widely separated and that all the visits of the physicians are made at the same hour. One is therefore unable to make more than one visit daily. At most hospitals the professors hold a clinic after their rounds, twice a week. It is best to ascertain the days selected for this clinic, and attend the different hospitals on those days. In this way one can visit three hospitals a week with some regularity, and devote the other days to going to special hospitals. The Hôpital de la Charité (Péter, Hardy, and Gosselin) in the Rue Jacob, 47; the Hôtel Dieu (G. Sée, Le Fort, and Vulpian), near Notre Dame; the Hôpital Lariboisière (Jaccoud and Duplay), near the North Station; the Hôpital Necker (Potain, Trélat, and Guyon); the Hôpital St. Antoine, in the Faubourg St. Antoine (Dieulafoy, Hayem, and Dujardin-Beaumetz), are all large hospitals, with five hundred to eight hundred beds, and offer a large material for study. If one desires to learn the methods of a particular man, it is best to attend that man's visits several times a week, and watch his cases, rather than to go from one to another, and miss the individual methods of each. By attending a visit in the morning, dissecting or doing laboratory work in the early afternoon, and hearing lectures later, one can make much out of a stay in Paris. If, however, one desires to see special cases only, much time will be lost which could be spent to better advantage in Germany.

An account of the opportunities of work would be incomplete if the private dispensaries of Paris were not mentioned. These are not under the government support, and do not belong to the "*Assistance publique*." They are located in small private houses, sometimes difficult to find, and are usually conducted by specialists. Landolt (Rue St. André des Artes, 10) and Galezowski (Rue Dauphine, 15) have such private clinics near the School of Medicine, where opportunities for studying diseases of the eye are very good. There are also several for treatment of diseases of the throat, diseases of women, etc. Their number and location vary from year to year, but they are usually mentioned with their addresses in the students' number of "*Le progrès médical*," published early in October. In most of these specialties there are weekly classes at the larger hospitals, but, as in London, special work, except in nervous diseases, is done in Paris at a disadvantage and at a loss of time.

It must not be forgotten by a student that lectures are delivered on anatomy and physiology at the Collège de France as well as at the medical school; and, when he learns that Ranvier and Brown-Séquard can be heard twice a week, he will not fail to walk up the Rue des Ecoles and find his way to their lecture-rooms. He will not regret the time spent in the effort, and he will come away convinced that in these sciences progress is constant and rapid.

The medical societies of Paris are numerous, and some are worth a visit. At the meeting of the Société Anatomique, held on Friday at 3 p. m., at No. 15 Rue de l'École de Médecine, the most interesting pathological specimens of the week from the various hospitals are to be seen, and the discussions, led by Cornil, the president, are animated and full of information. At the Société de Biologie, which meets at the same place on Saturday at 4 p. m., some of the most valuable results of original work in physiology and experimental therapeutics are announced by the foremost workers in Paris. Paul Bert is president, and Brown-Séquard, Péter, Bouchut, Bouley, G. Sée, Hardy, and Hayem are constant attendants. The Académie de Médecine (Rue des St. Pères, 39) meets on Tuesday at 3 p. m., and is also attended by prominent members of the profession, and its meetings are full of interest, as remarkable cases are frequently shown. The Société de Chirurgie, Rue de l'Abbaye, 3, Wednesday, at 3.30 p. m., is attractive to those who are watching the progress in surgical science.

The extent and thoroughness of the training obtained by the medical student in Paris have been incidentally shown in this description. The important fact that attendance at the laboratories and at the hospital rounds is obligatory, while the student may attend the lectures or not, as he pleases, deserves a moment's notice. The result of this is seen in the crowded lecture-rooms, for nothing will incite a keener interest in a theoretical lecture than a desire to get from it some information regarding a case under observation.

The examinations in chemistry, physics, and botany occur at the end of the first year; in anatomy, histology, and physiology at the middle or end of the third year, at which time the student has to make a dissection before a prosector; and in the other departments at the end of the fourth year. The final examination is practical as well as theoretical, each student being given a medical, obstetrical, and surgical case to examine for ten minutes, after which he is to give a lecture upon it. The examinations are conducted by three members of the faculty (the names changing daily), and are held at any time that the student may desire, all through the year, each man receiving his diploma after his examination is satisfactorily passed. There is no "commencement day." The number of medical students in Paris is five thousand, a small number being females, who are admitted to all the courses, and are uniformly treated with respect and courtesy. For a foreigner, all the courses are open freely, and there is nothing to pay. To one who visits Vienna before going to Paris, this feature is especially attractive, as the chief reproach to the medical school of the former city is its money-making propensity. In Paris one meets the most generous and courteous treatment, and feels at once at home.

Germany.—The student who starts for Germany in pursuit of medical knowledge may be embarrassed to know where to go. The number of German universities is large, as may be seen from the following list. Each has its medical department fully equipped, and about one quarter of the students are pursuing medical study.

German universities, with the number of students in each during 1883.

Berlin.....	3,900	Königsberg.....	863
Leipzig.....	3,111	Strassburg.....	823
Munich.....	2,017	Marburg.....	766
Breslau.....	1,532	Freiburg.....	721
Tübingen.....	1,400	Greifswald.....	659
Halle.....	1,377	Erlangen.....	575
Würzburg.....	1,091	Jena.....	570
Göttingen.....	1,083	Giessen.....	435
Bonn.....	1,061	Münster.....	326
Kiel.....	381	Rostock.....	217
Heidelberg.....	922		

The selection of one or more of these as places for study must depend entirely upon the object which the student has in view. Many desire to complete their knowledge in several branches of medicine by attending courses of lectures. Others wish to obtain a practical acquaintance with disease by seeing as many cases as possible. A third class go with the object of doing laboratory work in anatomy, physiology, or pathology. And, lastly, there are the specialists, who wish to limit their study to a single department. It is a well-known fact that

general medical study is best pursued in a large city, where the material for clinical instruction afforded by numerous large hospitals and dispensaries is extensive. Hence it is advisable that the first two classes of students should select Berlin or Leipsic as affording the best advantages for their purpose. It must not be supposed, however, that the smaller universities are lacking wholly in facilities for clinical instruction. Every one of them has a hospital containing between five hundred and eight hundred beds, in connection with its medical school. And to this hospital the country people living near the university town apply in large numbers, there being in Germany none of that feeling of reluctance in entering a hospital which is so often displayed by the ignorant classes with us. Even in the small town of Heidelberg there is ample material for the supply of eight clinics daily.

But in a large city there is, of course, a greater variety of cases, and the student can pursue a number of studies at once to greater advantage. The presence of such men at Berlin as Waldeyer and Hartmann in anatomy, Du Bois-Reymond and Munk in physiology, Virchow in pathology, Frerichs and Leyden and Senator in medicine, Schröder in obstetrics, von Bergmann in surgery, and Westphal in neurology, is sure to attract many students. Leipsic comes second with a corps of instructors hardly equaled in any other city. His and Flechsig in anatomy, Ludwig in physiology, Wagner in medicine, and Thiersch in surgery, are all teachers whose names are known wherever medical literature is read. In both these cities the hospital advantages are great and the material very large. The *Charité* in Berlin receives 12,000 patients yearly, and it is in the wards of this hospital that clinical instruction is given by Bardeleben, Frerichs, and Leyden. In Leipsic the new buildings of the medical school are grouped about the large municipal hospital in the south-east corner of the city, and the students can go from the laboratories to the wards with little loss of time. In Munich also, where Nussbaum and von Ziemssen hold daily clinics, the hospital is enormous, covering a large area and having divisions in which every form of disease is to be found. While no one German city stands in the same relation to Germany that Paris does to France, there is no doubt that in most departments of medicine the universities of Berlin and Leipsic lead all others. The student whose time is limited, and who has no special study in view, should choose one of these two places, as they furnish able instruction in all departments. A further attraction in the larger cities is found in the meetings of the various scientific and medical societies, which are well worth attending regularly, on account of the character of their membership and the interest of their proceedings. Probably in no city in Europe is a more notable body of medical men collected than in Berlin, at the medical society presided over by Virchow, where the discoveries of Koch were first announced and where the most accurate pathological discussions are carried on.

Among the smaller universities those of Strassburg and Heidelberg are decidedly the favorites with foreigners. At Strassburg the German Government is making every effort to strengthen the university, and with that end in view new and most commodious laboratories and hospitals have been erected and most able men have been selected as professors. Probably at no place in Germany is more good work done in the laboratories than in Strassburg. The physiological laboratory is directed by Göltz; the pathological work is done under the direction of von Recklinghausen, while Hoppe-Seyler has charge of the department of physiological and pathological chemistry, a subject in which he stands almost alone as a leader. The number of students working in the laboratories is large, but there are ample accommodations for all, and the personal attention given to each by professors and assistants is considerable. The laboratories are open from 8 A. M. to 6 P. M., but, if one desires to devote a part of the day to clinics, he can listen to the lectures of Kussmaul in the hospital, or watch Lieke as he operates in the surgical wards. In Heidelberg also the laboratory work holds a prominent place. Kühne, who ranks with Hoppe-Seyler, has a very large and perfectly equipped institute, and is not only an admirable instructor, but takes a personal interest in those who are working with him in physiology, and stimulates his students by his enthusiasm in his subject. In comparative anatomy few can approach Gegenbaur for thoroughness, and his laboratory attracts many students every year. But it is for pathology that Heidelberg has obtained a deserv-

edly high reputation. The laboratory, a well-arranged and very complete building, standing on the bank of the Neckar, within the hospital grounds, contains every requisite for pathological investigation. It is under the direction of Arnold, who, with his assistant Thoma (the inventor of the celebrated microtome), is always present, ready to assist the student in the details of mounting a specimen, to direct his attention to new lines of investigation, or to encourage him in original work. It is in such a laboratory that one gets rid of that cold reserve which exists too often here between professor and student, and begins to enjoy the relationship of fellow-worker with his instructor, which seems to obtain widely in the German colleges. In this laboratory the student is furnished with pathological material, is taught the technique of cutting and mounting specimens, is shown how to study them thoroughly when mounted, and is given as complete instruction in the subject as can be imparted anywhere. Whether he comes for the purpose of getting a general knowledge of pathology or to study in a special department, such as the structure of tumors or the diseases of some one organ, he will be able to attain his object equally well, and will be sure of individual attention and personal help. All the autopsies of the hospital are made in this laboratory with the students under the direction of Professor Arnold. One didactic lecture is given daily on pathology, and twice a week there is a practical course lasting three hours, during which time specimens are distributed among the class for each man to diagnose, by which means his knowledge is tested. To one who is unfamiliar with such work it offers all the attraction of novelty, and one who has pursued the subject in even the best laboratories at home can not fail to obtain valuable points and new methods. The criticism is often urged that Arnold requires, or desires, men to follow certain fixed lines of study, and does not encourage special and independent work. The advantages afforded for the study of surgery in Heidelberg are also very good. Czerny holds a clinic daily for three hours, and gives also theoretical and operative courses. He controls about one hundred beds in the hospital, and his reputation attracts patients of all classes from the whole of Baden. The medical clinics are now led by Erb and von Deutsch, and are also well supplied with material. Students can have cases in the hospital assigned them to take charge of and watch, with the power of reporting to the professor daily; and obstetrical cases are also given to practitioners in the lying-in asylum. The eye courses under Becker are celebrated, there being a separate ophthalmic hospital under his care. The attractions of Heidelberg as a summer resort add to the pleasure of a semester's work, and account for its holding its place as the favorite among the smaller universities.

The other universities are visited chiefly by specialists, who wish to work under one man on one subject. Thus some go every year to Würzburg to the laboratory of Kölliker or to attend the children's clinic of Gerhardt. To Halle, Volkmann attracts students by his lectures on surgery, his five courses on operations, and his brilliant clinic. Hegar's instruction in gynaecology at Freiburg is spoken of very highly by those who have been with him. The course of Pfüger in physiology at Bonn, and of Henle on anatomy at Göttingen, both in connection with laboratory work, are taken by a few.

The German student has to go through as long and as thorough a course of study as the Frenchman in order to obtain his degree of doctor, and then has to submit to a Staats-Examen almost as severe as his university examination in order to become a legally qualified practitioner. The time spent by most students in preparation is four years, but this is rarely passed in connection with a single university. It is the custom to study at one place during the first two years, and then during the last two to pass one semester each at four universities, and take the degree either from the last or from the first. Many do three years' work in Germany and then spend two years in Vienna, obtaining their degree there.

One of the chief features of the instruction in Germany is the teaching of the Privat-Dozenten. These young men hold subordinate positions in the university or hospital, and are constantly endeavoring by their work to secure the higher places of assistant professors. With this object they form small classes in special subjects, and, by the attractiveness of their lectures, operative courses, demonstrations, or private clinics, seek to draw students and obtain a reputation. It is frequently the case that the course of a Privat-Dozent is more profitable

to the student than that of the professor, and in many universities the lecture-room of the former will be crowded while that of the latter is deserted. To encourage this rising talent many of the universities set apart special lecture-rooms for the Privat-Dozenten, or offer them facilities for clinical teaching by assigning them a division of a hospital. Their number is sufficient to produce much competition for favor, and the rivalry acts as a stimulus to harder work. A professor who is content to repeat the same lectures from year to year, or who fails to keep abreast of the latest progress in his subject, soon finds that the students prefer to hear a more active man, though he may be younger and less experienced. And, as there is no compulsion about attendance at lectures and the students can go where they please, the result is usually that they flock to the better teacher. In every university catalogue it will be noticed that several men are announcing courses on the same subject. It follows, as a matter of necessity, that the competition for students will secure an excellence of instruction that can result only in benefit to both teacher and pupil. A stranger in selecting his courses should always consult some student who has been already at work, for not infrequently he will find that he can gain more from the course of a Privat-Dozent who is comparatively unknown than he can from the instruction of the more celebrated professor. The young teacher knows the wants of the student, his memory of his own needs being fresh, and he does his best to supply them. All the successful professors in Germany to-day have begun as Privat-Dozenten, and there are many Dozenten teaching small classes in small universities who are destined to attain the highest position in a few years. One of the chief reasons why the professors in German universities are so superior is because of their preliminary training as Privat-Dozenten, and the fact that they have been chosen on the principle of the "survival of the fittest." In France all positions are obtained by "concours," and the competitive examination determines every man's advancement. In Germany the vacant positions in a university are filled by appointment made by the Minister of Instruction on recommendation of the faculty of the university. That these faculties are watching the course of the Privat-Dozenten in every university and appreciate merit wherever found may be illustrated by the history of Nothnagel, now professor of clinical medicine in Vienna, and probably the most brilliant medical lecturer in the world. He graduated at Berlin in 1863. From 1864 to 1868 he was Privat-Dozent in Königsberg. He was then called as Privat-Dozent to Berlin, where he remained till 1870, when he received an appointment as assistant professor at Breslau. After two years Freiburg offered him the chair of materia medica, and two years later he was called to Jena as professor of clinical medicine and pathology. He left there only last year to take the high position of head of a clinic in the Vienna school. So long as the German universities thus select the best talent available in the whole country, it will not be surprising that their halls are crowded with students from the entire world.

The cost of instruction in Germany is moderate. Any foreigner who can show evidence by diploma of three years' work in medicine may obtain from the secretary an "*Erlaubniss*," or formal permission, to attend lectures on payment of twelve marks, half the matriculation fee. Others can matriculate at any time. The cost of each lecture course for a semester is thirty to forty marks, and the sum demanded for access to the laboratory about thirty marks, this including all materials used in working. It is customary for a student to take at least one course of lectures under the professor in whose laboratory he is studying, though this is not obligatory. The student will not find his expenses for tuition more than two hundred marks (fifty dollars) a semester in any university. Living is also cheap in German towns, and the student can secure a pleasant home in a small family, where his daily contact with its members will be an assistance to him in acquiring the language, for the moderate sum of eight to twelve dollars a week. A large income is, therefore, by no means necessary in order to spend a year in study abroad.

Vienna is to-day to the medical student what Mecca is to the Moslem. His life is incomplete—to say nothing of his education—until he has been there. From the time one lands in Europe he will hear the praises of the Austrian capital, and, though he may go with many prejudices, he will, in the end, be obliged to admit its attractions. The secret of that attraction lies in the fact that an enormous medical material is

utilized in the best possible way for the purpose of instruction. In other cities there are as many patients, as many students, as many teachers. But in no other are the three brought together in a manner so profitable to all. In the first place, most of the medical interest centers at the general hospital, and the student does not lose time by running about the city. Secondly, there are so many courses in every subject that every hour of the day can be utilized, even if one is pursuing a specialty. Thirdly, the courses, given to a limited number of students at a time, are compressed into six or eight weeks by being held daily for one or two hours, and thus the general student can, in the course of one semester, pursue a large number of different subjects, while the specialist can gain familiarity by repetition. Fourthly, most instruction is by means of clinical demonstration, the examination of patients by the student being the chief object of any course. And, lastly, the pathological material is immense, but not well utilized.

The Allgemeine Krankenhaus, situated in the Josefstadt, at No. 4 Alserstrasse, just ten minutes' walk from the center of the city, is the largest hospital in Europe. It is built as a series of quadrangles, with large open courts in the center, of which there are nine, the largest being 500 by 300 feet. The buildings are two and three stories high and very plain, there being no architectural display. They are constructed of brick, and, like most of the houses in Vienna, are covered with stucco. They are narrow, so that the wards, which run lengthwise, have light and air upon both sides. There is accommodation in the hospital for 3,500 patients, 85 resident physicians and surgeons, and over 1,000 attendants. The patients are distributed through 33 divisions, of which 6 are of general medicine, 5 of general surgery, 1 of thoracic diseases, 2 of gynecology, 3 of eye diseases, 2 of ear diseases, 3 of syphilis, 2 of skin diseases, 2 of mental diseases, 3 of obstetrics, 1 of throat diseases, and the remainder for private patients. Each division has from two to five separate wards—there being 122 wards in the hospital. In the year 1882 there were 23,565 patients treated in the hospital, and nearly 10,000 women delivered in the obstetric wards. This does not include the number of out-door patients, which has been estimated at 40,000. From these figures one can obtain some idea of the enormous material at the disposal of the teachers in the medical school. Their instruction is given within the hospital, there being large and commodious operating- and lecture-rooms in connection with almost every division. In the hospital there is every provision for the care of the patients, the entire institution being conducted at the city's expense, at a generous outlay of nearly a million florins yearly. The accommodations of the house staff are comfortable, and, in addition to their lodging, they receive salaries which vary from 360 fl. to 1,800 fl. yearly, according to the position held. These positions are obtained by appointment. A number of rooms are always to be obtained within the hospital by students; and, for one who is practicing in the obstetrical wards, it is an advantage to secure such accommodation. They may be obtained by application to one of the janitors at the gates. For the benefit of the staff and of students, there is a large reading-room and library in the hospital, where all the standard German works, and most of the German, French, and English periodicals (and one American weekly journal) may be found. Admission is granted to a foreigner on payment of 2 fl. a month. Though by no means so extensive as the library in connection with the Paris school, it is a much more attractive and pleasant room for reading. In the rear of the hospital are the pathological buildings, with the post-mortem rooms, the operative-course rooms, and the many laboratories. The pathological museum, a very extensive collection, is to be found here.

The St. Anna's Hospital for Children, which is near the General Hospital, has 360 beds, and in its outdoor department 7,000 children are treated annually. It is here that the clinic of Professor Wiederhofer and the private courses of Dr. Frühwald are held.

The Vienna Poliklinik, within two minutes' walk of the hospital, is used by the professors for purposes of instruction in all departments, and here "walking cases" of many kinds may be seen which are not to be found in the hospital.

The Wieden Hospital, 800 beds, and the Rudolf Spital, 900 beds, are used by their attending surgeons and physicians for clinical purposes, and are accessible to students, as are also their pathological departments.

But it is chiefly in the first three institutions named, and especially in the Allgemeine Krankenhaus, that medical instruction is given.

Clinical teaching is such a prominent feature in Vienna that it must be considered particularly, and at some length. More definite information can be given by taking up each department in turn.

Surgery.—The name of Billroth is known to every student of medicine in Europe or America, and it is natural that it should be mentioned first. His clinic is held daily from ten to twelve, except Saturday and Sunday, and is always crowded with students. Cases are brought in in rapid succession, are anesthetized before the class, and, after one of the students has been called down to examine the case and make the diagnosis, Billroth, or his chief assistant, Wölfler, operates. There are always from ten to fifteen assistants present in addition to a company of guests and the students, and, as the amphitheatre is poorly arranged, the opportunity for seeing the details of an operation are not very good. After the operation the case is removed, dressings being usually applied outside the operating-room. Thus many cases are brought before a class daily. Occasionally this order is interrupted and the professor will spend half an hour in explaining the pathology of a case, or in making a careful differential diagnosis. But, as a rule, the time is occupied by operations.

Billroth's two assistants give a number of courses in operative surgery, surgical dressings, and bandaging, and also take classes of students into the wards to examine and dress cases, or to watch the progress of patients from day to day. These courses are limited to ten students, and occupy six weeks. It is well, therefore, in this, as in other departments, for the student to put down his name for a course as soon as he arrives in Vienna, otherwise he may find all the places engaged at a time when he desires a course. The seats in the clinics are assigned at the beginning of each semester by the first assistant, and here, too, it is well to be on hand early in order to obtain a desirable place.

Professor Albert's clinic is more popular than that of Billroth, and his lectures and operations should be attended by the student of surgery. They occur at the same hour as Billroth's, and his material is even greater than that of his rival. Similar courses in operative and practical surgery are given by his assistants, Meydl and Lorenz.

In genito-urinary surgery there are numerous special courses. The lectures by Professor von Dittel and his operations in this field of surgery are largely attended, and in his division of the hospital every variety of diseases of the genito-urinary organs can be seen.

The daily clinic of Ultzmann at the Poliklinik is also crowded, and his course is as complete and satisfactory as any in the city. He devotes one half of the hour to the treatment of patients, and the other to lectures on the urine, especial attention being called to the diagnostic importance of its examination.

These are the principal courses in surgery, though under that head there are thirty-two courses announced in the catalogue. If any one is desirous to devote especial attention to this subject, he will find it possible to obtain almost anything he may desire by applying to one of the assistants at the hospital. They are ready at any time to give special courses provided a sufficient number of students—i. e., four to eight—will join, so that they shall receive an equivalent for their time and trouble. Such courses are somewhat expensive, but usually repay the student well.

The chief general medical clinics are those of Nothnagel and Bamberger, held every morning from eight to ten. In these clinics all classes of cases are seen. It is seldom that more than one case is discussed on one occasion, the patient being used as the text for a careful description of the aetiology, pathology, symptomatology, and treatment of the disease under observation. Occasionally one patient may be lectured upon for several clinics. At other times, several patients, illustrating different stages of the same disease, are brought in during one clinic, and frequently the same patient is shown several times at intervals to demonstrate the progress of the case. When a patient dies, the autopsy is performed in the presence of the class, when the case is one of any interest, and then the history and diagnosis are carefully reviewed in the light of the post-mortem, and the specimens shown.

A description of one of Nothnagel's clinics will convey some idea of his methods. The patient having been brought in, in bed, from one of

the wards which adjoin the lecture-room, one member of the senior class is called down by the professor and requested to examine the case. The questions asked by the student are often rambling and disconnected, and this gives Nothnagel an opportunity to speak of the proper method of getting the history of a case, a point upon which he lays great stress, and in which he insists upon a logical and exact order. The student is then required to describe the patient's condition, his bony formation, his muscular development, his state of nutrition, the condition of his skin, his facial expression, any peculiarities in his appearance, and the precise character of his pulse; in other words, to mention all the points which he should notice for his own information on first seeing a case. After this, the history which has been taken by the house physician is read. The attention of the student is then directed to the most prominent symptoms, each of which is taken up in turn, and, if possible, traced to its pathological cause, it being the great object of Nothnagel to produce in the student's mind a picture of the pathological process which is giving rise to the phenomena present. All the possible causes which could produce a symptom are elicited from the student, and then, as other symptoms are brought out, one or the other of these causes is eliminated until, by a synthesis of symptoms and an analysis of causes, the diagnosis is reached. In all cases a physical examination of each organ and a urinary examination are made before the class by the professor, and the result stated. If an electrical examination is necessary, it is made.

The importance of carefully eliciting every symptom in a complete manner is especially enforced. Then the professor sums up the case concisely, bringing into prominence the diagnostic points and making a differentiation. He also questions the student regarding prognosis and treatment, requiring a physiological reason for the use of any drug, with the exact dosage of each preparation available. To keep the attention of the class for two hours, to lead on the student in an encouraging manner, to bring together all the features of the case into a perfect picture of varying color and appropriate light and shade, and to dismiss them with a vivid recollection of the diseased patient—require an ability in analysis, a personal attraction of manner, a fluency of speech, and an amount of energy which few professors possess to the degree of Nothnagel. That he is successful is proved by the fact that nearly five hundred men attend his clinic daily, and many are obliged to stand during the entire time, in spite of the fact that the room is badly ventilated and the seats uncomfortable. The most perfect order is maintained throughout. For an hour during the afternoon Nothnagel's assistants take all those students who desire to go through the wards, and each has an opportunity to examine for himself the case which has been explained in the morning's clinic. Between forty and sixty take advantage of this ward work daily, and each student is then assigned to some new case, which he is expected to study carefully, to keep a history of, and to be ready to appear with in the clinic if the case is selected for a lecture. Thus the student who comes before the class with the patient is, to a certain extent, prepared, and is, therefore, less embarrassed than he might be if called to a new case. During their rounds the assistants show the processes of urinary analysis, and demonstrate under the microscope the sputa of tuberculous patients. The assistants give courses in physical diagnosis to all the students in divisions. They also give private diagnosis classes, the number of students being limited to six or twelve. In these classes, which are very much liked by foreigners, a patient is assigned to every two men, and, after they have examined him for half an hour, the assistant comes in, discusses the diagnosis, calls attention to any particular points of interest, and informs them what treatment is being pursued. Thus the student is brought into contact with patients and given a practical knowledge of disease. He has all the advantages which are obtained by a position of house physician in a hospital at home without its responsibility.

The clinic of Bamberger is conducted in a somewhat similar manner to that of Nothnagel, but, on account of his very feeble voice, the number of students who can hear is much smaller, and it is less crowded. His assistants give courses similar to those already described.

Professor Drasche, Professor Schrötter, and many Privat-Dozenten announce courses on general medicine, physical diagnosis and general diagnosis, and use the patients in their divisions for the purpose of in-

struction. In the Poliklinik, Stoffella and Oser have large numbers of out-door patients, who can be examined by the students. Thus it will be seen that there is no lack of material for study, and no difficulty of access to it.

The numerous deaths in the hospital, and the fact that in almost all cases autopsies are made, makes the pathological instruction an important feature in the medical work. Autopsies are made every morning between eight and eleven, there being, as a rule, about six, occasionally as many as fifteen in a day. Students can be present and witness the post-mortem made by Professor Kundrat, and hear him dictate the careful description of each organ examined. If they do not wish to spend so much time, they can attend his noon lecture on pathology, at the close of which all the specimens of the day are demonstrated to the class; or they can join one of the limited courses given by his assistant, Dr. Zemann, in which the same specimens are shown to a few men, and they are allowed to examine and handle them. Dr. Zemann also gives a course on the diagnosis of pathological specimens, which is of great interest and service to one who desires to learn anything of gross pathology. Professor Kundrat and his assistants also give short courses on the methods of making autopsies, in which the students are allowed to do the work themselves. A very good course in gross pathology is also given by Dr. Weichselbaum in the dead-house of the Rudolf-Spital, and in his laboratory a course may be taken on microscopic pathology which is unequalled in Vienna. The laboratories of Stricker, Spina, and Basch are crowded with students, mostly Germans, for foreigners find the practical work in the hospital so important that they seldom devote their time to microscopy while in Vienna. These laboratories are, however, well arranged and conducted, and the supply of specimens to work on is unlimited. It has been stated that ten thousand women are delivered yearly in the hospital. These cases are as available for instruction as those in the other wards. There are three obstetric divisions. Those of Späth and Carl Braun are open to students; that of Gustav Braun is used for the education of midwives. Women are received in all stages of pregnancy, and await delivery in the hospital; but the majority of cases do not enter until they are in the first stage of labor. When the pains begin the woman is sent to the division which is on service at the time, there being a regular rotation of the three divisions, each serving twelve hours. Each division has one ward for deliveries and several other wards for the care of patients after labor, to which they are removed three hours after the birth of the child, and where they are kept usually for ten days, when they are considered able to go out.

Every student who desires to practice in the obstetric wards takes a ticket for a course of lectures on obstetrics, and this ticket admits him at any time to the wards to witness deliveries. It also entitles him to place his name on the roll among three hundred other names to await his turn for service. Every day names are posted in each division, and, as each patient can be examined by a certain number men, and there are frequently twelve or fifteen patients in various stages of labor, each man has an opportunity to examine and deliver several cases when his name is down. In addition to these four names, two others are posted by the assistant in charge, and these are selected from a list of names, on which list any one desiring to practice may put his signature. If a man desires to work constantly in obstetrics he will therefore obtain the right to practice in both divisions and keep his name down on both voluntary lists, and in this way he can be assigned to a ward at least three times a week, and sometimes oftener. During vacations—that is, between March 1st and May 1st and between August 1st and October 1st, and during the first six weeks of each semester—all the names are selected from this voluntary list, and then a practitioner can serve about as often as he desires.

The wards of each division are under the direction of two assistants, each serving on alternate days and performing all the operations which are necessary. These assistants give several private courses in obstetrics. One course is called a "touch course," in which women in all stages of pregnancy are examined, and the diagnosis of the stage, the position, the presentation, etc., are made by the student; all the obstetric operations are described and their indication stated; in fact, a complete course on obstetrics is given, with the advantage of a patient to illustrate every detail. In one of these courses, which are limited to

three or four men, a student can learn more than by a year's reading, and no man should stay in Vienna a month without obtaining this instruction. A second course is in operative obstetrics, in which all kinds of operations are taught upon the cadaver or mannikin, each student being obliged to perform them himself under direction of the assistant. No one can expect to be allowed to operate in the wards unless he has taken one or more of these courses with the assistant, but, having taken them, he is sure of an opportunity to put his knowledge to use.

Courses in gynecology, gynecological diagnosis, and operations are also given by the same assistants. These courses are good, because they are given by young men who are enthusiastic in their work and eager to attract students by the excellence of their teaching. Those of Ehrendorfer and Pritzel are especially recommended. Bandl's class in gynecology at the Poliklinik is a practical one, students being required to make diagnoses constantly. In the hospital, in addition to the wards of Carl Braun, where operations may be seen every morning, there are the wards of Dr. Pawlik, Dr. Funk, and Dr. Schlesinger, Privat-Dozenten in this department.

The diseases of children are seen in Vienna to great advantage, there being numerous clinics open to the student. Professor Wiederhofer lectures daily at the St. Anna's Children's Hospital upon cases brought into his class, and then takes the students through the wards, so that they can follow the progress of cases from day to day. His assistant, Dr. Frühwald, gives similar instruction at another hour.

In the Carolinen Kinderspital, and in the Rudolf Kinderspital, clinics are also held three times a week, the material being as great as at St. Anna's. At the Poliklinik, Professor Monti holds one of the best courses in Vienna, devoting half an hour to the examination of cases, and the other half to a course of lectures on the diseases of children, which are full of practical and useful instruction.

Among the specialties, that of skin diseases is naturally first. The Vienna school, founded by Hebra and ably conducted by Kaposi and Neumann, attracts students from the entire world. The clinics are enormous, there being frequently 60 to 100 cases presented daily at Kaposi's class. Diagnosis is the great object in the lectures, and is secured by comparison of patients presenting similar symptoms. Probably in no other specialty is it more necessary to see cases, and more difficult to acquire knowledge by reading, and in no place can more cases be seen than in Vienna. The morning clinic of Kaposi and the afternoon clinic of Neumann can be supplemented by visiting their wards with their assistants, or by attending some of the other practical courses by Privat-Dozenten, of which there are nearly a dozen. Nor must it be supposed that treatment is neglected. Various methods can be seen in the wards, and the results watched from day to day. The foreigner will be especially interested in going through the bathing establishment connected with Kaposi's wards, where every form of bath is given, and where the treatment by continued immersion is to be seen, patients being shown who have not been out of the bath for six months. Severe burns are treated by keeping the patient continuously in water, with immense relief from pain and with good result. Syphilis is classed with skin diseases in the hospital, but special lectures on it may be heard from Zeissl and Neumann.

Diseases of the eye come near to skin diseases in importance in Vienna, where Jäger and Arit and Stellwag have kept up the reputation of the school founded by von Graefe. There are three divisions in the hospital devoted to this class of cases, and in these the specialist will find enough to do to fill up all his day. In addition to the general clinics, there are operative courses, courses on refraction and accommodation, and courses on the use of the ophthalmoscope. Every graduate in Vienna must pass an examination on diseases of the eye, and hence these classes are all filled with students. One can follow the rounds from 8 to 10 and see operations, then watch a clinic from 10 to 12; from 2 to 4 take the admirable course of Mauthner in the pathology and treatment of eye diseases, and from 4 to 7 use the ophthalmoscope under the direction of Dinmer or Borysiewicz. In diseases of the ear, the courses of Politzer and Grüber in the wards of the hospital, and of Urbantschitsch at the Poliklinik, leave no form of malady unexplained.

Diseases of the nervous system and of the mind are taught in Vi-

enna by Meynert, Rosenthal, Leidesdorf, and Benedikt, both by lectures and by clinics, in the hospital and in asylums. Several Privat-Dozenten give short courses in the wards, and one who follows Nothnagel's clinic will notice the pleasure which he takes in showing cases in his own favorite department. In the laboratory of Meynert his system of brain anatomy is presented in all its details, a collection of microscopic specimens unequaled in Europe may be examined, and the pathology of insanity, as far as it exists, may be learned.

There are many courses given on diseases of the throat, all of them for the purpose of giving a student opportunity to acquire skill in the manipulation of the instruments and in local applications to the parts diseased. Schrötter, Schnitzler, Fischer, Störk, and Chiari announce lectures and clinics. The student will obtain most satisfaction from those classes in which the number is limited to four or six, as he will then receive personal attention, which is of great use to the beginner and a satisfaction to the skillful diagnostician. It is therefore necessary to register one's name for such a course several weeks before it begins. The student will soon make the acquaintance of Frau Gehley, one of the characters about the hospital, who for twenty years has made her living by allowing students to examine her throat. She has most perfect control over her organs, and can demonstrate any part of her larynx and touch any part with the probe herself. A few hours' practice upon her will teach a beginner as much as an ordinary course.

It will be seen from this review that there are few subjects of medical knowledge in which the student can not find satisfaction in Vienna. The complaint will be rather that too much is offered for him to take; that there is a true *embarras de richesses*. A few practical suggestions may therefore be allowed which are derived from personal experience: Let the student go to Vienna during a vacation—i. e., in March or in August—and occupy himself in the study of obstetrics, which he can do to the best advantage at this time, taking operative and touch courses of at least two assistants, and practicing in the wards. Any extra hours he may have can be devoted to some of the specialties—eye, skin, or throat, or to diagnosis classes in the wards—as many of the courses of the assistants are kept up during the vacation, and they are ready to form classes if a sufficient number (four to ten, as the case may be) apply. When the term begins he can then choose his studies without being obliged to allow for obstetric work in the wards, which otherwise may interfere with his taking pathological or operative courses. Whatever clinic may be selected, the student should follow that one continuously, for there is usually a method in the selection and order of cases demonstrated, as he will find by reviewing his notes at the end. The great drawback in Vienna is the fact that several courses which one may desire to take are held at the same time, and the student attempts to solve the difficulty by attending all irregularly, thus losing the benefit of each as a whole. It is better to sacrifice the least important, and then, by means of the courses of the Privat-Dozenten in that department, make up for the loss of the lectures of the professor. The fact that most of these courses take but six weeks enables one to hear a number of them during one semester.

The fact that no reference has been made to anatomical or physiological work indicates that it holds a secondary place in the Vienna school. It can be done if one desires to do it. But, when one has access to such clinical material as is offered in the hospital, he feels that his time should be devoted to that most practical side of medicine rather than spent upon the rudiments. And, furthermore, the facilities for anatomical work are far better elsewhere, as already indicated in the section on Paris. It may be mentioned, however, that the anatomical rooms and the physiological laboratory are situated on Währinger Strasse, in the rear of the hospital and opposite the Poliklinik. The buildings are old and somewhat dark. There is, however, no lack of material for dissection, and if one desires demonstrations in anatomy, the prosecutors are ready to give special courses which shall comprise whatever the student desires. In physiology, the lectures of Brücke and Exner are open to the student, but, on account of certain peculiarities of the lecturers, they are not very popular.

The chief medical society of Vienna is the Academy, of which all the professors are members, and the meetings of which they attend regularly. Billroth was president last winter, and Arlt vice-president. At their meetings, held on Friday evenings at seven o'clock in the old

university building, some of the most remarkable cases in the hospital are shown, and many carefully prepared and interesting papers are read. The visitor should not fail to attend these meetings, which are open to any medical man.

To a student who has been at Paris, one of the chief features of study in Vienna will be its expense. In Paris everything is free. In Vienna nothing is free. He can not escape the idea that the hospital is used as a money-making institution. But he will soon perceive that he is receiving a fair equivalent for his outlay, and will not regret the Thalers spent. The professors' courses are from ten to twenty florins for the semester (a florin equals forty-two cents). The majority of the small private courses are twenty florins. A diagnosis course can not be obtained for less than twenty-five florins. An operative course is the same. The obstetric touch courses are fifty florins for twenty-five lessons. A student must allow at least three or four hundred florins a semester for courses. This is much in excess of the amount demanded in Germany, but to the American student does not seem unreasonable. For the reason that his studies may make his hours of leisure irregular, the student will find it much more convenient to hire a room near the hospital and take his meals at some of the restaurants in the vicinity. Good rooms can be obtained at prices varying from twenty to forty florins a month, according to comfort and location. The boarding-houses are to be avoided, as they are all very poor. Meals in restaurants will cost from two to five florins a day. Expenses will, therefore, average in Vienna considerably less than in New York.

A few Americans go to Prague for purposes of study. The character and methods of instruction there are very similar to those in the capital, and the advantages for the study of obstetrics under Breisky are fully as great. The hospital is, however, much smaller than the Allgemeine Krankenhaus of Vienna, and neither the material nor the ability of the instructors is sufficient to attract many students. One who can not be satisfied in Vienna should at once abandon the study of medicine and return home.

It is hardly necessary to refer to other universities, since none of them can compete with those already described in offering attractions to the medical student.

The institutions of Italy and Switzerland are well equipped and present attractive catalogues, but few foreigners are found among their students, and their practical courses are inferior to those in Germany.

The medical student just about to start is often uncertain where to go. The writer would recommend the following plan:

Make a short stay in London to see the best men and obtain an idea of English methods. If, by contrast later with German men and methods, they appear preferable, the student can return to England; if not, he will have a longer time for work on the Continent. Go next to Germany, and select one of the smaller university towns for the first three months' work. Here whatever time is not occupied in acquiring the language can be spent in the study of pathology in a laboratory whose director will be able to give his instruction to the beginner in his own language. Strassburg, Heidelberg, or Leipzig may be chosen for this purpose. As soon as the first semester is over go to Vienna for obstetric work during the vacation, and while there obtain whatever information is desired regarding the special study which is to be pursued. Both the specialist and the general student will find one semester in Vienna indispensable, and will probably desire to take a second one. The second vacation may be passed at Berlin, Leipzig, or Munich, where special courses are to be obtained between the semesters. From Germany go to Paris, so arranging one's plans as to spend the months of April to July in that city. If French is not understood, it can be learned in Germany during the preceding winter, or a competent teacher can be obtained in Paris at the International Society of Teachers in the Rue Royale. If one's time is very limited, spend it all in Vienna. If it is unlimited, visit as many universities as possible, but do not spend less than an entire semester in each, for little good will be obtained from hearing but half a dozen lectures from any one man. Above all, remember that it is less the actual knowledge obtained than the new methods of acquiring knowledge which are to be prized and utilized. If the student returns imbued with the French enthusiasm combined with the German thoroughness, his medical trip will be a permanent source of congratulation.

Original Communications.

STENOSIS OF THE TRACHEA: THREE CASES.*

By E. FLETCHER INGALS, M. D.,
CHICAGO.

DURING the past year I have treated three cases of obstruction of the trachea, the results of which I think sufficiently satisfactory to render brief histories of them of interest to this association.

CASE I.—J. M., aged about forty-five. I was called to see the patient first in October, 1882. I found him suffering greatly from dyspnoea, with loud sonorous and labored respiration; he was unable to lie down, and moved with great difficulty. The legs and feet were oedematous and painful, and the urine was scanty. Frequent paroxysms of cough and excessive dyspnoea occurred, during which the patient's life was often in imminent danger.

He said that he had been under treatment about eight months for bronchitis and asthma. He had but little fever, and there was no pain except that in the legs. The shape of the chest was normal, but there was considerable falling in of the soft parts during respiration.

An irregular area of dullness could be detected in the upper sternal region and extending about an inch to the left of the sternum.

Loud sonorous râles, heard best over the lower part of the trachea, were propagated over the whole chest. The lungs themselves were healthy, and the heart and blood-vessels yielded no abnormal signs. No difficulty was experienced in swallowing. The larynx was normal. There was no interference with the function of the recurrent laryngeal nerve, and the upper half of the trachea, which was all that could be seen, was natural in appearance.

The stomach was healthy, and, excepting the small secretion of urine, there was no evidence of disease in the other abdominal organs.

From the seat of the râles and from the symptoms, I was satisfied that the patient's distress was due to obstruction at the lower part of the trachea; and, from absence of all the signs of aneurysm excepting dullness, and from absence of symptoms of the cancerous cachexia, I concluded that the obstruction was due to sub-sternal thickening. This I presumed to be of syphilitic origin, though, owing to the surroundings, I could not obtain the history on this point for several days.

The patient was given hydragogues, cathartics, and iodide of potassium in moderate doses, upon which he improved for a few days, but at the end of a week he seemed in such a critical condition that a consultation was held. At this time, while the young wife was absent for a moment, the patient confessed to having had syphilis seven years previously.

The case appeared hopeless, but it was decided to increase the dose of the iodide of potassium to twenty grains. This was ordered to be taken, with half a glass of water, every sixth hour, alternately with ferruginous and bitter tonics. Anodynes to quiet the cough, and cathartics as needed to keep the bowels free, were also administered at irregular intervals for several days.

The patient soon began to improve, and gradually mended

for two or three weeks, when the dose of the iodide was increased to thirty grains, three or four times a day.

The administration of the remedy in these large doses was followed by most happy results, and at the end of two months the patient expressed himself as much better than for many months before; however, about six weeks later, the symptoms of obstruction of the trachea grew worse, and did not yield to the remedy in this dose.

The dose was then increased to sixty grains three times a day, and again rapid improvement followed. Before long the patient was able to leave the house, and subsequently, for several months, he visited me at irregular intervals at my office. He continued most of this time to take the large doses of iodide of potassium.

Finally, hoping for more complete relief, he determined to go to the Hot Springs of Arkansas, where he remained for two or three weeks, at the end of which time a telegram announced his sudden death. He was reported to have died of asthma.

In this case life was undoubtedly prolonged many months by the use of large doses of the iodide of potassium.

CASE II.—A. H. H. came to me complaining of hoarseness, violent paroxysms of cough, and severe dyspnoea, which had troubled him for two months. A careful examination of the chest revealed signs similar to those in the preceding case, excepting that there was no abnormal dullness. The larynx was normal, and the upper third of the trachea, which was all that could be seen on account of a sharp bend, was healthy.

In this case the seat of the râles and obstruction could be ascertained by auscultation to be the lower part of the trachea, but the cause of the obstruction could not be ascertained; however, a history of syphilis, six years previously, induced me to order the iodide of potassium in large doses.

Subsequently this was substituted by the iodide of sodium, the dose of which was increased to one hundred and twenty grains three times a day. The remedy was given at first in doses of forty-five grains each, three times a day, the dose being increased ten or fifteen grains with each succeeding day until the amount of six drachms daily had been reached. This was continued three or four days, and then the drug was suspended for three or four days, when the patient began again with doses of forty-five grains, which were gradually increased as before. Under this treatment he steadily improved, and was soon able to attend to business. At the end of three months he reported himself better than for several months before.

He is still doing well, and taking the medicine part of the time, but the case is not completed. There has been no return of the severe symptoms, and he is able to attend to business regularly.

CASE III.—A. P. came to me thirteen months ago, complaining of hoarseness and dyspnoea on active exertion. He was a robust man, weighing about two hundred pounds, and seemed, aside from the foregoing symptoms, to be in the best of health.

Upon laryngoscopic examination, I found a small, conical projection from the anterior part of the trachea in the median line, half an inch below the glottis.

This was three sixteenths of an inch in diameter near the base, about a quarter of an inch in altitude, and was surrounded by a congested and swollen mucous membrane.

The mass itself was of a deep-red color for about two thirds of its altitude, but the remainder, at the apex, was of a yellowish-white color, giving it the appearance of a pustule.

Mild astringent applications were made two or three times, and the sulphide of calcium was given internally for about a week, when the pustule opened, its contents escaped, and it shrank to about one third of its original size. In two or three

* Read before the American Laryngological Association, May 13, 1884.

weeks this had mostly disappeared, but the mucous membrane remained considerably swollen.

Two or three weeks later a similar growth appeared in nearly the same position, which ran the same course as the preceding, and left increased thickening of the mucous membrane, especially at the sides of the trachea.

This growth was soon followed by another, and it by a fourth, after which the thickening of the mucous membrane at the sides of the trachea, half an inch below the true cords, closely resembled the appearance of the ventricular bands when nearly approximated.

A chink was left between the two sides not more than three sixteenths of an inch in width by five eighths of an inch in length. Respiration was constantly greatly obstructed, and it became difficult for the patient to make the slightest exertion. Paroxysms of distressing suffocation, probably due to collection of the secretions, were of frequent occurrence, especially at night.

At this time another growth made its appearance near the anterior end of the welt on one side, and, as it slowly increased in size, steadily aggravated the difficulty in respiration so as to render the patient's condition dangerous. I was then compelled to do tracheotomy.

After the operation there were no unusual symptoms, and at the end of three weeks, the growth having disappeared, the chink was nearly as large as after the preceding growth. From what I learned of this gentleman's history, although there had been none of the common symptoms of specific disease for twenty years, I determined to give him iodide of potassium, which I administered in from ten- to twenty-grain doses for several weeks previous to the tracheotomy, but without good result.

About three weeks after the operation, at the suggestion of a friend who had treated the patient a few years previously for some obscure affection of the nervous system, I began the use of large doses of the iodide of potassium, starting with forty grains at a dose four times a day, and increasing the size of the dose each day ten grains until he took one hundred and twenty grains four times every day. This dose, which gave him four hundred and eighty grains daily, was continued about ten days, and then all medicine was suspended for a few days, when it was resumed in doses of forty grains, which were steadily increased as before.

Under this plan of treatment I saw the thickened tissues melt away, so that at the end of three weeks the caliber of the trachea was of full size. Subsequently the medicine was continued at intervals, being taken about half of the time for several months, in doses varying from thirty to sixty grains, three times a day. The patient, having left the city a few weeks after the operation, to be gone several months, used his own discretion in taking the medicine.

The cannula was not removed from the trachea until after the patient's return to the city six months after the operation. The opening closed so promptly that at the end of two days no air escaped from it.

In the first of these cases the large doses of iodide of potassium prolonged life many months. In the second case the iodide of sodium restored to usefulness a man who without it could have lived but a few weeks, and in the third case the iodide of potassium relieved the patient from the necessity of permanently wearing the trachea-tube, and perfectly restored his voice.

I have presented these cases merely as suggestive of what may occasionally be accomplished with enormous

doses of a remedy which I believe should usually be administered in small doses. I am well aware that given indiscriminately it would be productive of most serious results, but used judiciously, in properly selected cases, it is an agent of inestimable value in some of the most dangerous affections we are called upon to treat.

64 STATE STREET, CHICAGO.

DISCUSSION.

Dr. DE BLOIS: With regard to the treatment of laryngeal stenosis by the iodide of potassium, I have seen a case in consultation in which the patient was unable to take mercury. Large doses of iodide of potassium were given with marked improvement, as the swelling in the larynx almost entirely disappeared from the effect, it was believed, of the use of the drug.

Dr. SHURELY inquired of Dr. Ingals whether in his first case the swelling was entirely of the mucous membrane, or whether the tracheal glands were involved.

Dr. INGALS replied that there was no reason to believe that the glands were involved.

Dr. LANGMAD: I believe that laryngeal stenosis, in consequence of swelling, is very much more commonly the result of syphilis than is supposed. I agree with Dr. Mackenzie's view as to the proclivity of syphilis to show itself in the upper air-passages. It will be found that congenital syphilis in particular is the cause of many cases of death which have been attributed to croup, laryngeal diphtheria, etc., stenosis having taken place from subglottic swelling due to the syphilitic poison. Adults, as is well known, are not to be excepted. In the case of a woman suddenly attacked with urgent dyspnea at night, I was called, and found subglottic swelling, corresponding to the condition described by Dr. Ingals. I suspected syphilis, and made immediate inunctions of mercury, and gave iodide of potassium internally, at the same time preparing for tracheotomy should it prove necessary. Recovery after the inunctions was rapid and complete. Some years ago I was requested to care for a patient of Dr. Knight's during his absence. I was sent for and found the patient suffering from urgent dyspnea from subglottic swelling, and adopted the same treatment as in the other case. Relief was almost immediate. In looking back over my early dispensary experience, I can recall several cases of death in young children which I now believe might have been obviated by active specific treatment.

Dr. DELAVAN: A few years ago a woman came to me complaining of a slight degree of laryngeal dyspnea which, although the laryngoscopic appearance resembled chondritis vocalis inferior hypertrophica, I believed to be due to syphilis. She stoutly denied specific disease, however, and disappeared from observation for about two months, when she returned, suffering so severely that tracheotomy seemed necessary. Examination showed that the trachea was almost completely occluded at a point immediately below the glottis. The patient finally admitted having acquired syphilis about ten years before. Before resorting to operative measures, large and frequently repeated doses of iodide of potassium were administered, with almost immediate relief to the dyspnea, and within a wonderfully short time, with the entire disappearance of the subglottic stenosis.

Dr. BOSWORTH: The weight of evidence seems to be in favor of the use of large doses of iodide of potassium. My belief is, from experience in other than syphilitic cases, that iodide of potassium is a dangerous remedy in tracheal swellings or oedema. I have been accustomed to employ it, but with some hesitation, until in one case, in which it produced iodism, it resulted in such swelling of the mucous membrane of the air-passages as to render tracheotomy imperative. Since that time I have con-

find myself to the internal administration of mercury or to mercurial inunctions. The question arises, whether Dr. Langmaid's success was not due to the mercurial inunctions rather than to the iodide of potassium. I rely mainly upon mercury in the treatment of the late manifestations of syphilis.

Dr. LANGMAID thought the improvement which took place in his cases was due to the mercurial inunctions rather than to the iodide of potassium.

Dr. INGALLS, in closing the discussion: I am glad Dr. Bosworth has criticised the use of the iodide of potassium. In one of the cases mentioned in the paper I feared such a danger, and was induced to continue its use in large doses only by the assurance of the physician under whose care the patient had been, that large doses had been given before with impunity. It does not always require large doses of the iodide to produce a coryza. I know of patients in whom from five to ten grains will give rise to the symptom, while large doses produce no such effect. The custom of giving the drug uniformly in large doses is pernicious.

SOME REMARKS ON TWO HUNDRED AND EIGHTY-EIGHT DEATHS.

By OSCAR J. COSKERY, M.D.,

PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS,
BALTIMORE.

In Vol. XXVI of the "New York Medical Journal" I reported 112 deaths, with tables and remarks similar to those following. The present number makes a total of 400. The object of both papers is to assist in discovering whether there is any connection between the time of day or night, the state of the thermometer, barometer, direction of wind, etc., and death, and, if so, what that connection is. The small number of cases does not go very far toward this consummation, but, as the experience of one observer, may be of service. They were nearly all hospital patients, and in the majority a post-mortem was held.

29.75.....	7	30.25.....	16		
29.80.....	9	30.30.....	16	Total.....	288
29.85.....	9	30.35.....	10		
29.90.....	18	30.40.....	5		

For table of ages, sex, cause of death, etc., see following pages.

If we examine these tables, we find that there were 129 deaths occurring between midnight and midday, and 159 between midday and midnight (*vide* Table No. 2). But, if we take the most chronic causes of death—old age and consumption—and add them to those reported by me in a paper published in Vol. XXVI of the "New York Medical Journal" of 112 deaths, as stated, we find that the total of 400 recorded cases will give exactly 73 between midnight and midday, and 73 between midday and midnight; so that the proportion of 10 per cent. in the number of deaths from all causes is, if we can be at all guided by this small number of 400 cases, reduced to zero.

If we take Table No. 2 and divide the twenty-four hours into sixths, commencing at 1 A. M., we find that the same number of deaths (46) took place in the second, third, and fifth; that the fourth and sixth showed the highest proportion (56 and 57, respectively), while the first, or that from 1 A. M. to 4 A. M., inclusive, the lowest, or only 37. These added to the table of 112, above alluded to, will give the following:

Of the 400 deaths:

- 60 occurred between 1 and 4 A. M., inclusive.
- 62 occurred between 5 and 8 A. M., inclusive.
- 69 occurred between 9 and 12 A. M., inclusive.
- 80 occurred between 1 and 4 P. M., inclusive.
- 61 occurred between 5 and 8 P. M., inclusive.
- 68 occurred between 9 and 12 P. M., inclusive.

400 Total.

The table of the ages at which death occurred calls for no comment.

Of the total number of cases recorded (400), we find 141 from affections of the respiratory organs. Of these, 89 died between November 1st and April 30th (inclusive), while 52 only died during the remaining six months.

Of the 288, 170 died between thirty and fifty, inclusive, while, if we take the whole number (400), we notice that only 212 died between those ages, or very little above one half. It must be remembered that nearly all the cases recorded in both papers were in hospital practice, which will account for the large proportion at the mid-period of life.

In Table No. 4 we find, besides the ages at which death took place, the month in which it occurred from all causes. If we add these results to those reported of the former 112, in the total of 400 we have more during January, February, April, July, October, and November. June, August, September, and December show the smallest mortality. The conclusion, we think, obvious. Great heat, and what we

recognize in this locality as months during which great climatic changes take place from day to day, are exceedingly prone to hasten death.

Of the table showing the state of the thermometer at or nearest the time of death, it is only interesting to note that the highest mortality took place between 30° and 50°, inclusive. In the table of 288 the number was 121. Of the

total 400, 168. This may only point out that somewhere near is our mean temperature.

The barometric table calls for little comment. It only shows that the greatest number of deaths did not take place while the barometric tension was least—an idea that has been advanced.

I am fully aware that but little has been proved by these tables; still, if one single grain has been added to our sum of knowledge, the object has been gained. In spite of even more careful records of *one million* cases, people will go on dying only when *their* time of fulfillment shall have arrived; but if such records show that in the great majority of cases, at or about one particular hour, or during one particular condition of the barometer or thermometer, death takes place, then, I contend, something has been achieved.

SOME NEW CONSIDERATIONS

ON THE PATHOLOGY AND TREATMENT OF ACUTE PARENCHYMATOUS METAMORPHOSIS OF THE KIDNEY.

By WILLIAM HENRY PORTER, M.D.,

ASSOCIATE PROFESSOR OF PATHOLOGICAL ANATOMY AND CLINICAL MEDICINE IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; CURATOR OF THE PRESBYTERIAN HOSPITAL; MEMBER OF THE NEW YORK PATHOLOGICAL SOCIETY, ETC.

The physiological researches of the past few years have thrown much light on the excretory functions of the kidneys, while at the same time both the histological and the pathological anatomy of the organ have been studied with great advantage. Accordingly, we are now in a position to understand better than ever before many topics that have been obscure and confusing in the matter of Bright's disease, as it is commonly known.

If, then, we have in mind the newly acquired physiological data, and, with them in view, study the pathological changes, it will be easy to see that the common term, Bright's disease, covers a number of renal lesions which fall naturally into groups that are quite distinctive, and which have, in nearly every instance, their clinical characteristics so peculiar that they can be recognized at the bedside nearly as well as at the post-mortem table.

In the present article it is proposed to take up one form of a single group, in which group the morbid changes affect the cellular elements, and it may be here stated that the data are obtained by a study of cases which have been followed from the ward to the post-mortem examination. It is hoped that the views here advanced will contribute not only to our notions of the disease from the pathological standpoint purely, but will serve to show the relation the changes have to the general condition of the patient, so that our treatment in such cases may be better directed.

It must be recognized that there are two subdivisions of the excretory apparatus of the kidney—one composed mainly of the coil of blood-vessels in the glomeruli, or Malpighian tuft, the other of a portion of the tubules, through their epithelium.

The glomeruli are generally believed to filter the water and inorganic salts held in solution; it is also thought that

sugar, albumin, and peptones pass out through the glomeruli, the epithelium of the tubules eliminating the urea and the crystalline nitrogenous substances.

Now, as the passage of solutions through an animal membrane depends to a great extent upon the pressure exerted, the rapidity with which the urine is excreted and its amount naturally vary with the blood-pressure in the glomeruli, and, consequently, the greater the pressure in the vessels, the greater will be the excretion, and *vice versa*. Accordingly, the pressure in the vessels of the glomeruli may be increased—

1. By any increase in the force and frequency of the heart's action.

2. By contraction of the arterioles at large or in areas other than those of the kidney.

3. By relaxation of the renal arterioles, either alone or with contraction of other areas.

Or the pressure may be diminished—

1. By any diminution in the force and frequency of the heart's beats.

2. By dilating the arterioles at large or in areas other than the kidney.

3. By contraction of the renal arterioles, either alone or with relaxation of other areas.

The function of the glomeruli is comparatively simple, being immediately under the control of the vaso-motor system. Physiological experiments have shown that a division of the spinal cord below the medulla greatly diminishes the flow of urine. The explanation is, that large vascular areas are cut off from their communication with the medullary vaso-motor center, which, associated with the shock to the spinal cord, produces a great fall in the general blood-pressure.

With this relaxation of the renal artery an augmented flow of urine would be expected, but the great fall in the general blood-pressure completely overbalances the effect produced upon the renal artery and diminishes the pressure in the vessels of the glomeruli. Stimulating the spinal cord below the medulla affects the cord in an opposite manner from division, but produces the same effect in reference to the quantity of urine excreted. This is explained by the renal artery becoming so firmly contracted that the general increased blood-pressure is overbalanced, the artery being, as it were, ligated, and the pressure upon the vessels of the glomeruli diminished or removed. Therefore, opposite effects upon the cord produce precisely the same action upon the glomeruli.

Section of the renal nerve produces relaxation of the renal artery, increased pressure in the capillaries of the glomeruli, and an increased flow of urine. Section of the spinal cord, after division of the renal nerve, arrests the polyuria by increasing the general capillary capacity outside the kidney, thus reducing the general blood-pressure, and in this way establishing again a normal pressure in the glomeruli. Stimulation of the spinal cord, after division of the renal nerve, still further increases the flow of urine by diminishing the general capillary capacity outside the kidney, thus increasing the general blood-pressure in the glomeruli.

Section of the splanchnic nerve, by which the kidney gets its principal nerve-supply, increases the flow of urine

by relaxing the renal artery, but not to so great a degree as division of the renal nerve only. As the splanchnic nerve is distributed to the whole splanchnic arcade, the capillaries of which are dilated, consequently the blood-pressure brought to bear upon the glomeruli does not rise so high. Stimulating the splanchnic nerve contracts the renal artery and arrests the flow of urine.

From these observations, it is quite clear that the quantity of water discharged from the kidney is governed, to a large extent, by the vaso-motor system.

The function of the epithelium, on the other hand, is much more complex; but it appears to excrete the effete material of the system, chiefly urea—the product of tissue metamorphosis.

In the experiments of Heidenhain upon the lower animals, sodium sulphindigotate, known as indigo-carmin, was injected into the blood, and, after the expiration of a certain length of time, the animals were killed and their kidneys carefully examined. In these experiments the indigo-carmin was found entering the epithelium through the rods of Heidenhain, passing out of the epithelium into the lumen of the uriniferous tubules. In other experiments a length of time was permitted to elapse after the first injection, which previous experience had shown was sufficient for the complete elimination of the pigment by the epithelium. Another quantity was then injected into the blood; in this instance the elimination of the second injection of pigment was found to be incomplete, as if the cells, exhausted by their previous efforts, were unable to perform the extra work thrown upon them. Thus, so far as indigo-carmin was concerned, it was proved that, as effete material, it was eliminated by the epithelium. These experiments were followed by those of Nussbaum on amphibia; the newt was the animal chosen for experiment, the kidney of which has a double vascular system—an arterial, from which the glomeruli receive their blood-supply, and a venous, by which its uriniferous tubules are surrounded. These two blood-supplies have no connection, the one coming from the renal artery, the other from the bifurcation of the femoral veins, an arrangement peculiar to these animals. If one of these channels is closed, what is excreted by the other can be readily ascertained. The amount of certain substances was increased, and others not normal to the urine were brought about by injections into the systemic circulation. The result of these experiments showed that water, peptones, albumin, and sugar were found in the urine previous to the ligation of the renal artery, but that they disappeared upon the performance of the operation; urea, however, continued to appear in the urine after the artery had been tied. When indigo-carmin was injected into the circulation after ligation of this vessel, no urine was found in the bladder; but the pigment could be traced through the epithelium into the lumen of the uriniferous tubules. It appears that the excretion of water, although almost entirely confined to the glomeruli, was undertaken to a slight extent by the epithelium, probably for the purpose of dissolving the urea and rendering its excretion less difficult than it otherwise would be; but, when the additional stimulus of an increased amount of effete material excited the cells to a more than

ordinary action, the flow of water from them became more abundant.

Further than this, experiments have as yet shown nothing; but even these go far to prove that, in the normal state, the glomeruli supply almost if not quite all the water and inorganic salts of the urine, while to the epithelial cells lining the uriniferous tubules is left the task of excreting the products of tissue metamorphosis. By applying these physiological data to our present pathological knowledge, we are enabled to understand many conditions heretofore very obscure.

We now approach a subject concerning which there has been much uncertainty among pathologists, and this is, the relation between parenchymatous change and inflammation.

In a general way, this term—namely, inflammation—may be said to include one or more of a series of changes occurring in the living tissues as the result of an irritation or injury, provided it does not completely destroy the vitality of the part, which may be induced in a variety of ways, either by an external or by an internal agency.

The exciting injury may be extrinsically direct when produced by chemical or mechanical irritants; intrinsically indirect when produced through the blood- or lymph-channels; indirect, as when internal organs become inflamed after exposure to cold. So-called idiopathic diseases, the causes of which are internal or imperceptible, come under the head of indirect, for in all cases the inflammatory process must be produced by some injury.

The usual order of events when an organ has been attacked is as follows: Acute hyperæmia—more accurately speaking, determination of blood to the part—followed by stasis; the escape of the liquor sanguinis; the migration of the white and a diapedesis of the red corpuscles. Also among its results may be ranked the increase in size and number of the original elements, a deposit of adventitious material, changing in character the elements attacked, and death, with its necessary loss of substance.

It occasionally happens that changes in the blood and blood-vessels constitute the only signs of inflammation, as in acute meningitis, where death ensues before the exudation of all the constituents of the blood takes place; but, for a full definition of a typical case of inflammation, all of the foregoing are necessary.

Considering all these changes essential to our conception of a true inflammatory process, it seems difficult to see what relation the change called parenchymatous metamorphosis bears to inflammation.

What actually happens to the cells is that they are overworked by an attempt on their part to free the kidney and, secondarily, the system of an excessive amount of the incompletely formed products of tissue metamorphosis, or some extraneous poison. The experiments of Nussbaum with indigo-carmin go to sustain this explanation. In this metamorphosis, as in his experiments, the epithelial protoplasm undoubtedly loses its power of elimination, and becomes altered by the effete material and caused to undergo various retrograde changes, known as cloudy swelling, fine and coarse granular metamorphosis, and fatty transformation.

With these introductory explanations, we come to our

first division of this group of renal lesions, commonly classed as Bright's disease.

ACUTE PARENCHYMATOUS METAMORPHOSIS OF THE KIDNEY.—This disease, commonly known as acute parenchymatous nephritis, is that lesion of the kidney in which the epithelial cells lining the uriniferous tubules undergo metamorphic changes—namely, cloudy swelling and fine and coarse granular and fatty infiltration—but in which there is no change in the blood-vessels or interstitial tissue.

This metamorphosis occurs in connection with, or as a complication of, scarlet fever, pneumonia, diphtheria, small-pox, typhus fever, typhoid fever, yellow fever, cholera in bad cases, puerperal fever, septicæmia, pyæmia, and acute yellow atrophy of the liver. This condition may possibly be met with during the early stage of cirrhosis of the liver, severe cases of jaundice, and various pigmentary diseases. The exact relation of the pathological condition to these three last conditions is as yet somewhat uncertain. This lesion is also the result of poisoning by arsenic, phosphorus, antimony, and copper; and, in some rare cases, is said to develop without known cause. This list comprises those diseases in which the exciting cause is some original and impalpable poison, which greatly interferes with the normal nutrition of the body, diminishing the perfection of its products and increasing their amount and rapidity of formation. The incomplete change thus produced differs from the normal physiological process in the large amount of effete material generated and the great rapidity with which it appears in the system. Great irritation is necessarily produced in the whole animal economy by the combined action of the original poison and of those incomplete products of tissue metamorphosis circulating in the blood; and to their combined action the phenomenon known as elevation of temperature is believed to be due. However this may be, the kidneys, which are the great eliminating organs of this variety of waste products, endeavor to remove from the body, by means of their epithelial cells, the irritating substances which are producing such deleterious effects upon the system. At first they may be successful, but, as the labor thrown upon them is increased, they may become exhausted (as in Heidenhain's second injection of indigo-carmin), and the process of excretion is less complete. Their protoplasm becomes infiltrated with minute particles of irritating substances, such as effete material, pigments, etc., which cause them to swell and to lose their transparency. The weakest of them undergo a progressive change which ultimately results in a complete granular or fatty metamorphosis, and final destruction of their vital property. This process is certainly not inflammatory, but one of transformation and death, which is caused by an unduly prolonged struggle on the part of the epithelial cells to accomplish a work too great for their capacity. As the disease advances, the cells fall from their place on the wall of the uriniferous tubules, and appear in the urine as casts and cast-matter. The tubules, thus deprived of their epithelial cells, have in some places only basement membrane to form their wall; but, as only isolated cells undergo degeneration, the damage done is repaired according to the general law of regeneration and proliferation of the epithelial elements, and the wall of the

tube is restored to its normal condition after the complete subsidence of the disease, provided the chronic form is not developed.

A kidney in the condition of acute parenchymatous metamorphosis is enlarged, but it may be normal in size in some few cases. The capsule is normal in thickness, does not adhere to the underlying tissue, and leaves the surface of the kidney perfectly smooth upon its removal. The cut surface in the early stage presents no marked change by which this lesion can be positively recognized by the unaided eye. Later on it is pale, and the pyramids are less distinct than normal, but to the unaided eye they appear more distinct on account of the abnormal pallor of the cortical portion.

This lesion develops four degrees of change in the renal epithelium: *First, Cloudy Swelling.*—The condition known as "cloudy swelling" is one in which the elements are swollen by the imbibition of an albuminous fluid, and the protoplasm has become turbid. *Second* in sequence is the stage of finely granular metamorphosis, in which the epithelium is cloudy, but also infiltrated with fine granular particles, some of which are oil globules of minute size, and others granular detritus; probably from the incomplete products of tissue metamorphosis drawn from the blood, and in part from the further destruction of the epithelial protoplasm itself. *Third* comes the coarse granular change, which is simply a more advanced degree of the former, with more abundant and larger fat droplets. The *fourth* is the fatty transformation, where the protoplasm is entirely destroyed and replaced by fat globules, causing a destruction of their substance and an abolition of their function.

It seems quite probable that the cloudy and mucoid change is due to the retention of a small quantity of effete material in the protoplasm, thus causing this imbibition and transformation of the protoplasm. The fine granular, too, is a further change, due to the retention of a quantity of these irritating substances now perceptible in the cell, and a commencing disintegration of the protoplasm with a development of minute fat droplets. The retention of a still larger amount of effete material produces the coarsely granular metamorphosis, or a more advanced disintegration of the protoplasm, and an increase in the size of the fat droplets. In the last (*fourth*), or fatty change, so large a quantity of the products of incomplete tissue metamorphosis, pigments, etc., remains in the cells that their normal outlines are obliterated, and the protoplasm is now destroyed by fatty degeneration.

Early in the disease, the cells having swollen rapidly, while the kidney capsule remains unstretched, the lumen of the tubules is entirely occluded, and under the microscope the tubules are tortuous instead of straight. This, of course, refers to the straight tubules, and not to those normally convoluted; the latter, however, are considerably distorted.

In the milder forms the change in the epithelial cells is confined principally to the cells of the cortical layer and those lining the glomeruli.

In more advanced cases the cells of the pyramidal tubules also become involved. The degree of transformation

of the epithelial cells and the extent of territory implicated will depend wholly upon the intensity of the cause and its duration.

After the lesion has lasted for some time, what remains of the lumen of the tubules may be found to contain single or masses of transformed and desquamated epithelial cells, which appear like the material of which casts are made up.

Various forms of casts may occasionally be found in the lumen of the tubules.

The stroma is not involved, and the blood-vessels remain unchanged.

This lesion occurring, as it does, in connection with severe diseases, or as the result of some of the acute attacks of metallic poisoning, the symptoms referable to the nephritic metamorphosis are not well marked at first. Ordinarily, the symptoms of nephritic disease may be classified under four headings—three rational, and a urinary. The former are divided into cephalic, alimentary, and general. The cephalic are occipito-frontal headache, contraction of the pupils, injected conjunctivæ, lesions of the retina and optic nerve, drowsiness, convulsions, and coma. The neuro-retinal lesions will be considered more minutely in studying the lesions of the kidney, in which they are more frequently met with, for in this form they are rarely seen.

The alimentary symptoms are dyspeptic in character; they are nausea, vomiting, loss of appetite, disgust for food; diarrhœa is often a prominent symptom.

Those classed as general are œdema, commencing first in the subcutaneous connective tissue under and around the inferior eyelid, œdema of the inferior extremities, watery effusions into all the serous cavities, œdema of the superior extremities, and general anasarca. Œdema glottidis may occur. If the disease lasts for any length of time, a peculiar waxy, almost translucent, pallor of the skin may be developed. This, however, is seldom seen, except in that form following the chronic metallic poisoning.

With this form a large number of the rational symptoms are masked by the severe symptoms of the disease which it complicates; but those that do attract attention are usually œdema of the eyelids and feet, undue severity of the cerebral symptoms of the primary disease, and a diminution in the quantity of urine passed *daily*. These symptoms are followed speedily by those of a more acute character. The patient complains of a severe headache and drowsiness, rapidly followed by convulsions and coma. There may be associated with these cerebral symptoms, or independently, some nausea and irritability of the stomach, which often usher in severe vomiting and diarrhœa. The œdema may now become very marked and be followed by dropsy of all the large serous cavities. Dimness of vision also occurs in some of these cases, but is due to interference with the optic centers, and not to any lesion of the optic nerve or retina. As the disease progresses, the symptoms become more urgent, the drowsiness is followed by stupor and delirium, the urine may be entirely suppressed, and the patient lapse into a state of coma which is usually followed by convulsions and death.

During the course of the disease, which seldom lasts more than a few days, the cephalic, alimentary, and general

symptoms may not be associated as above described. In some cases, especially those which occur complicating scarlet fever, pneumonia, typhoid fever, and other acute febrile diseases, only those symptoms referable to the nervous system appear, and headache, accompanied by dimness of vision, drowsiness, stupor, delirium, and coma, follow each other in rapid succession; and, if the disease does not take a more favorable course at this point, convulsions ensue, speedily followed by a fatal result. In other cases the alimentary symptoms present themselves, and these cases are the ones which are most apt to terminate in chronic parenchymatous metamorphosis; they are the result of mineral poisoning.

Urinary symptoms are always present in all forms of the disease. The urine is high-colored, and in reaction the specific gravity is above normal, usually varying between 1.025 and 1.030; but, when the quantity passed is considered as compared with the normal daily quantity, the specific gravity is found to be below normal. Albumin is always present, and in very great quantities as a rule, but in some appearing only as a trace, or to the amount of one or two per cent., by volume; in other cases to the amount of from ten to fifty per cent.; while in the most severe types of the disease it may completely solidify the urine when boiled, so that, if the test-tube is inverted, no water flows away.

On microscopic examination early in the disease, small hyaline, epithelial, nucleated, and fine granular casts and granular *débris* are seen, while at a later stage the coarsely granular and fatty casts make their appearance; as the disease advances, the casts will increase in size.

The *diagnosis* is readily made by remembering the causes, and by an accurate urinary analysis in reference to casts. The only disease for which it might be mistaken is acute diffuse nephritis. In the latter disease we find blood and blood-casts in the urine; but in this lesion neither occurs.

The *prognosis* is always grave, and especially so when this lesion exists as a complication of acute diseases. In scarlet fever, if convulsions occur, the patient rarely, if ever, recovers; while in pneumonia, diphtheria, typhoid fever, etc., the first symptom of acute parenchymatous metamorphosis renders a favorable termination almost impossible, although there are instances in which patients recover even with this severe complication; they are, however, rare.

In those cases which result from mineral poisoning the immediate danger is not so great; but the disease is very apt to lapse into the chronic variety, which ends fatally in the course of a few years.

In *treating* this lesion of the kidney, its method of production should be kept constantly in view. It should be remembered that it is not of an inflammatory nature, but that it results from too much work being thrown upon the kidney, and that, in its efforts to relieve the system, it undergoes this metamorphosis. With this light upon the subject, the great object in the way of treatment is to prevent this excessive amount of work being forced upon this gland.

There is but little doubt that the idea that elevation of temperature or heat is the damaging element in disease has been much overestimated, and the *cause* of the increased

heat been too much neglected. The increase of body-heat should only be looked upon as a *symptom*, produced in part by the irritation of the original poison, and in part by the too abundant and incomplete products of tissue metamorphosis, excited by the poison and circulating throughout the system.

All we can do in reference to neutralizing the original poison is to make the hygienic surroundings as perfect as possible, and to supply the patient with a large quantity of fresh air.

The original poison, in a measure, is probably eliminated from the system by the kidneys, and also aids in damaging the epithelial protoplasm.

With such a condition as this, the kidney makes an effort to rid the system of this excessive amount of effete material, while at the same time it receives less nutriment than in health, and, consequently, is very likely to suffer irreparable damage.

The application of cold to the body in such conditions as these, according to well-established physiological laws, still further interferes with tissue metamorphosis and adds new fuel to the fire. Many cases have undoubtedly developed a fatal renal complication in this way. It often happens that, following a cold pack or bath, the cerebral symptoms increase in severity, the temperature rises higher, and albumin presents itself in the urine for the first time; a speedy and fatal termination soon ensues by an induced renal complication. A striking example of this kind was observed in a case of *sunstroke*. In this case, at the commencement of the attack there was a trace of albumin in the urine; but, following the repeated application of cold to lower the temperature, the quantity of albumin rose to 50 per cent. by volume, and all the urinary symptoms of acute parenchymatous metamorphosis presented themselves. Subsequent post-mortem examination confirmed the diagnosis in regard to the renal lesion. Remembering these facts, the kidney should demand our first attention in all these severe diseases and in cases of acute metallic poisoning, but especially in the former. Every effort should be made to aid the kidney during this severe strain and guard it against this transformation, and not wait until this metamorphosis has actually developed and then try to cope with so formidable a malady.

In these cases our attention should be directed to the other excretory channels—namely, the skin and alimentary tract—and every effort exerted to cause them to perform the largest possible amount of work. By so doing, we relieve, to a considerable extent, the increased strain upon the kidney.

Cold applications to the skin should be avoided. The skin should be kept moist and active by bathing in tepid water, or with tepid water to which a little alcohol has been added.

In bathing the sick, one rule should be rigidly enforced. After sponging a portion of the body, the nurse should rub the skin of that part perfectly dry with the bare hands before another portion is bathed. There is nothing more uncomfortable than to be left wet and clammy after bathing. On the other hand, nothing is more refreshing and

soothing to a patient than such a bath, provided the skin is dried in the way here suggested. The skin is also rendered more active—one great object to be attained.

Diaphoretics may also be used to advantage, *jaborandi*, or its alkaloids, standing first upon the list for promptness and certainty; but in these severe forms of disease its use would be contra-indicated, as it is sometimes depressing in its effects. The liquor ammonii acetatis, or spiritus ætheris nitrosi, may be found serviceable in keeping up free activity on the part of the skin; they also act slightly as diuretics, especially the latter.

Alcohol, which is often called for in these febrile diseases, acts as a diaphoretic and diuretic; it also retards oxidation, thus being of service in three ways.

The bowels should be acted upon as freely as the pre-existing condition will admit. In typhoid fever, little can be looked for in this direction; aside from this fever, yellow fever, and cholera, they should be moved at least once every day.

Treatment referable to the kidney is of the greatest importance. The main object is to increase the watery constituents to the maximum, so that the effete material necessarily passing through the renal protoplasm shall be in as dilute a solution as possible.

To accomplish this object, large draughts of water, demulcent drinks, and various mild mineral-waters, should be freely administered.

As medicinal diuretics, *tinctura ferri chloridi*, *digitalis* and its preparations, are the only ones to be used. The tincture of iron is an invaluable remedy, acting as a non-irritating diuretic, and enables the blood to carry more oxygen, thus aiding in bringing about a more perfect tissue metamorphosis. It is most serviceable as the disease advances and tends to assume a more persistent form.

Digitalis and its preparations are about the only safe remedies during the early stages of this lesion. It is a non-irritating diuretic, and acts principally by contracting the arterioles, and possibly by stimulating the heart and increasing the general blood-pressure; in this way we increase the pressure upon the glomeruli. It probably has less effect upon the renal arterioles than on the rest of the circulatory system, otherwise we should diminish instead of increasing the flow of urine. Further investigation will probably show that it only acts when there is venous congestion of the inter-tubular plexus of veins. Some have advanced the idea that this drug has a specific and yet unexplained action directly upon the kidney, especially upon the Malpighian tufts. The condition of this inter-tubular plexus may be the cause of this so-called specific effect.

The potassium salts are contra-indicated as diuretics, as they depress the heart's action and relax the arterioles. Their action as diuretics is ascribed to their power to increase oxidation and tissue metamorphosis, and in this way force more work upon the renal epithelial cells. They are therefore injurious for three reasons: *First*, they weaken the heart; *second*, they relax the whole arterial system; and, *third*, they increase the effete material to be thrown off by the epithelial protoplasm.

When opiates are used in this form of renal lesion as

nerve-sedatives, a fatal termination often results, if it is not the rule. In some forms of acute uræmia, morphine, hypodermically administered, may be followed by good results, but usually it is not considered a safe remedy.

The application of dry cups to the loins, followed by warm poultices, will be found very serviceable, especially if the renal symptoms become at all severe.

ON THE PREVENTION AND TREATMENT OF PUERPERAL FEVER

FROM AN ÆTIOLOGICAL STANDPOINT.

BY W. D. SCHUYLER, M.D.

(Continued from page 235.)

TREATMENT OF THE PUERPERAL WOMAN, WITH REFERENCE TO
THE PREVENTION OF THE PUERPERAL FEBRILE DISEASES.

HAVING determined by the foregoing, first, that the puerperal condition in itself, and uninfluenced by heterogeneous causes, in a general and extended sense, is not greatly prone to take on the puerperal febrile maladies, and, second, that these febrile maladies include, ætiologically considered, two essentially different diseases, each depending upon its own special and distinct pathogenesis, the indications for their prevention become reasonable and clearly differentiated, and their fulfillment correspondingly easy.

First. Treatment of the Puerperal Woman in Private Practice.—It has been shown that the puerpera, in a general and extended sense, especially as her tendencies are manifested in private practice, is not liable, without exposure to the proper contagium, or unless for some other especial cause, to develop the puerperal febrile maladies—namely, either puerperal fever or puerperal septicæmia. There is, therefore, no indication for the application of elaborate or unusual preventive measures against their occurrence in her case.

Furthermore, having been taught to rely with confidence upon Nature's methods, having been influenced by the general perfection of those methods to accept her teachings as precedents, and, more, having been led to consider her functional operations—where such have not been counteracted by morbid causes—as safe and conservative for the individual and the race, I can not now think that, with respect to her most important function—the process of generation—there should naturally inhere such marked susceptibility to danger, or that her manner of cleansing and restoring the genital apparatus after parturition is not safe and salutary. Hence, upon the ground of induction, of general experience, and of my own practice, I can not accept the teachings of Dr. Thomas, that every woman who is about to bring forth should be treated as one about to go through the perils of a capital operation, or that in every case the offensive fluid called lochia poisons—or is likely to poison—the system of the parturient woman through her lacerated and unprotected genital tract. And, therefore, I can not acknowledge that the prophylactic measures he advises should be adopted in all midwifery cases, or that it borders on criminality not to subject women in private practice, even among the wealthy, who can command every safeguard, to systematic aseptic rules.

The view and deduction just set forth relative to the non-susceptibility of the puerperal woman in general to contract the puerperal febrile maladies, and the consequent non-necessity for subjecting her to systematic aseptic rules, apply to the great number of puerperæ met with in *private practice, who are to be attended by a physician having private patients only.*

Where, however, a puerperal woman of private life is to be confined in a lying-in institution—especially in an institution where puerperal fever is endemic, or where she is to be attended by a physician having an infected lying-in service, or a physician who is a curator of dead subjects, or who is a consultant who has been exposed to the fever contagium or to surgical erysipelas—then, under either condition, the case is different, and the private patient, so considered, takes on the status of one who is in an exposed lying-in institution, or who resides in an endemic habitat; and the preventive indications in her case correspond with the measures indicated under any degree of exposure.

For the private, non-infected, non-exposed patient, on the one hand, certain measures are always justifiable, and should be secured where time and convenience allow of it. Her confinement-chamber should be selected for its sunny and cheerful aspect; it should be as roomy as may be, and easily ventilated. In selecting it, smells should be avoided, and, if possible, a room should be chosen having no stationary water-fixture. If a stationary basin can not be avoided, then such fixture should be tightly closed, not only by keeping the stopper in the bottom of the basin (which so many think sufficient), and the latter full of water, but the overflow escape into the waste-pipe should also be closed with corks. Furthermore, to insure safety, the basin should be emptied and renewed daily. And these precautions—from non-observance of which I have witnessed slow convalescence, unusual debility, deranged nutrition, constipation, prolonged lochial discharge, and the occurrence of painless and extensive mammary abscess—should be continued for two months, or longer, or until a convalescent condition is established. The matter of sewer-malaria I feel has not yet received that attention which its importance in a city, where so much organic matter goes to waste, demands. Strict attention to personal cleanliness for the patient should never be neglected, and all refuse or excreted matter should be immediately removed. The woman's diet should be looked after according to the indications her condition suggests, whether it demands much or little food, tonics, or the like; and her functional requirements should receive prompt attention. If there is any reason for apprehending that infective influences are present from any source, *a small quantity of sulphur may, with advantage and little discomfort, be burned in her room daily.* Attentions during labor do not require special directions, beyond the fact that all should be accomplished with the least fatigue to the woman and with the least violence to the parts engaged. As a general precaution against puerperal septicæmia, *the completion of labor should include, in all cases, a thorough evacuation of the womb of placenta, membranes, and clots, and the induction of a firm tonic contraction of that organ.*

But for the hospital patient, on the other hand, or for one whose physician is a visiting surgeon at a lying-in institution, not only are *all prophylactic measures*—besides those general precautions just referred to—proper, but it must be admitted that *their neglect "borders very closely upon criminality."* It is upon the ground of an especial requirement for consultants and hospital physicians, and their appreciation of the necessity for extraordinary measures in hospital and in private practice alike, that we are able to reconcile as reasonable the necessity—*from their point of view*—of the elaborate prophylactic measures urged by Dr. Thomas for all cases, and the equally unnecessary precautions (for the general practitioner) advocated and practiced by Dr. Garrigues.

While upon this subject, and before closing, I would remark, as already alluded to, that I do not consider the rules laid down by either of the gentlemen mentioned injurious; on the other hand, they would probably be productive of benefit, if applied in all cases; and their presentation to the profession must result in much good. I have only endeavored to show that, in the great majority of private cases, they are unnecessary, that therefore they are not reasonably demanded, and that, for this reason, a neglect to carry them out is, as before stated, not a criminality.

Second. *Prevention of Puerperal Fever.*—For the prevention of this form of puerperal disease, (1) we must provide against the development of the contagium; (2) the contagium having been developed in any certain region or habitat, and being in such habitat endemic or epidemic, we should protect the puerperæ of such region or habitat against an attack, and equally we should prevent its spreading to puerperæ who are within such contagious environment.

To prevent the development of the specific contagium of puerperal fever, we must entertain clear notions as to its origin. While this point has already received attention, it may be referred to again in this connection. This contagium has been recognized as epidemic, and, evidently, it develops anew in lying-in hospitals. From these sources it is propagated by contagion, or is contracted by infection.

(a) That it originates *de novo* in the wards of lying-in hospitals, especially if to the emanations which are developed therein is added the malaria (nosocomial) of a general hospital, appears most conclusive from its frequent reappearance in Bellevue Hospital during the past twenty years, and until that service was removed to the Emergency Hospital; and from its appearance in the latter hospital from its opening up to the present time, as also from its reappearance, or almost continuous presence, in Maternity Hospital since the origin of that institution.

Its probable mode of development in the Emergency Hospital has already been alluded to, and, as a matter of pathogenesis, is very interesting, and instructive. The lying-in ward of the Emergency—according to information derived by me at the office of Bellevue Hospital—is twenty-five by fifty feet, and has high ceilings. As already stated, it is held that, if over-crowding is not practiced in this ward, if not more than fifteen puerperæ are accommodated therein at any one time, puerperal fever (unless brought in from outside) will not develop in it. But if over-crowding is

practiced, and if from twenty to thirty patients are confined therein at one time, soon malarial symptoms begin to be manifest, then puerperal fever is developed, and still later puerperal, peritonitic, and contagious fevers occur.

From this interesting observation of very probable fact—which quite accords with general opinion upon this point—an aggregation and intensification of hospital lying-in emanations from over-crowding, combined with bad ventilation, and very probably, where lying-in wards form a part of a general hospital, with emanations from various noxious, septic, zymotic, cadaveric, or erysipelatous influences—in a word, with nosocomial malaria—are competent to develop it anew.

(b) What the special influence is that develops this poison when it occurs epidemically—as it has prevailed at various times and in various places—it is not so easy to determine. But that malaria, of some peculiar character, gives rise to the first manifestation of trouble, which trouble anticipates a full but later development of contagium—as in hospital cases—there can be little doubt.

Therefore, the indication for the prevention of the development of the contagium of puerperal fever in lying-in institutions is to *avoid over-crowding, and, at the same time, provide a free, ample, and adequate ventilation.* Again, as fumigation with burning sulphur evidently kills this poison, therefore daily disinfection of lying-in wards by this means, especially where over-crowding is unavoidable, should be practiced. Furthermore, as a preventive of the puerperal maladies, and as a wise and humanitarian measure to prevent a normal function from degenerating into a dangerous pathological condition, *all lying-in institutions should be removed from, and be for ever entirely disconnected with, general hospitals.* If the evidence which may be obtained by studying the histories of the lying-in services at Bellevue, Emergency, Charity, and Maternity Hospitals is competent upon which to base correct judgment, it is a matter of the greatest importance that the lying-in services in connection with those institutions should be discontinued. Considering the number of young and healthy mothers who have contracted puerperal fever, and hopelessly succumbed to it, under the management of combining a lying-in and general hospital under one roof, who might otherwise have lived out their days, and some of them probably been alive yet to-day, it is plain that the obstetric division of the city's eleemosynary work should be located in a home of its own in a salubrious environment, and away from general hospital influences.

Not knowing definitely what are the ætiological influences governing an outbreak of epidemic puerperal fever, we can not anticipate the disease by preventive measures. We can only adopt measures to prevent the puerperæ of an epidemic region—as soon as the boundaries of such are determined—from having the malady. This is best accomplished by their removal. While successful treatment of these cases may be practiced by the measures advised by Dr. Thomas or by Dr. Garrigues, yet, as there are chances of failure by any aseptic plan through some miscarriage of measures, the only safe procedure is that just advised.

In all cases, where possible, puerperæ should be removed from every endemic, epidemic, or infected habitat.

The manner in which puerperal fever is generally spread is by contagion. The indication for the prevention of this result is equally clear, i. e., to prevent exposure of the woman to the poison by herself or by its conveyance to her by another person. A woman rarely exposes herself. That puerperal fever may be conveyed to a parturient woman by a third person, by the doctor, while it may still be a question, is quite probable. In view of the physician being the possible carrier of the contagion, it is right where he has been exposed that he should act upon the affirmative of such possibility, and proceed to carry out either one of two preventive measures: (1) He should employ a substitute to attend to his obstetric practice for the time, or (2) he should treat his patient preventively, according to Dr. Thomas's or Dr. Garrigue's plan, or to both combined, for in this matter he can not be over-zealous.

Third: *For the prevention of puerperal septicaemia* the indications are also causal. The causes of this idiopathic puerperal malady are found in varying forms of autogenetic infection, or may reside in inoculation. The former possibly may be due to a retained decomposing placenta, to decomposing membranes, to degenerate lochia, or to decomposing retained blood, either or all of these becoming septic and infecting the woman by absorption through some laceration or wound of the generative tract or at the placental site. As septicaemia may occur from retained placenta after abortion, where no laceration of the generative tract occurs; and, on the other hand, as frequent lacerations occur, and as placenta and clots are frequently retained and undergo more or less decomposition, without setting up puerperal septicaemia, we may conclude that some other cause, a general morbid constitutional condition, rather than conditions wholly local, determines the disease. The general causal condition may be some predisposing dyscrasia, some state of physical depression, or an existing disease; the patient may be suffering from Bright's disease, or her system may be depressed and her nutritive functions imperfect from malarial poisoning or other cause. Her social condition may be the cause of depression or anxiety, or her surroundings may be unfavorable and may contribute to septic or zymotic states.

The preventive measures to be practiced against the occurrence of puerperal septicaemia are identical with those which should be observed in every case of labor for the protection of the woman against the *general, or usual*, dangers of child-birth; they are therefore not to be considered as special.

They are: First, the womb should be thoroughly emptied of placenta, clots, and membranes; second, the organ should be caused to undergo firm contraction, as the completion of the third stage of labor. In general, these measures are all that is required; but, where other conditions, evidently favorable for promoting the development of sepsis and zymosis, and therefore septicaemia, exist, they must be met by the measures indicated by each condition. Uræmia, general malaria, nosocomial malaria, erysipelas, or any special dyscrasia, should receive especial and prompt attention. If a woman's condition is markedly adynamic, and her nutritive status is such that a low form of vital action is going

on; if the condition is thought favorable for the development of septicaemia, it should be corrected by a tonic, stimulant, and promptly supporting course.

If there are reasons for concluding that septic development is going forward, whether within the vagina or uterus, from whatever cause, then measures should be adopted at once to prevent the absorption of putrid material and its results. A speculum examination should immediately be made, to confirm such diagnosis, to determine the site and the nature of the trouble, and the offending material should forthwith be removed. If bits of placenta, membranes, or clots are found in either portion of the generative tract, they may be removed by forceps, by scraping, or by any other procedure, and, after such removal, the affected part should be carefully washed out with a bland, non-irritating, aseptic injection. If the mass creating the morbid state is in the vagina, it will not be necessary to carry the injections into the womb; but, if the latter cavity is the seat of the trouble, then it should be injected without hesitation.

A septicæmic action is generally, if not always, developed in a system depressed; hence, while the local trouble is being cared for, a general tonic and alterative treatment is necessary.

After these general measures have been applied, and one thorough washing of the canal has been given, I would counsel no further interference, the use of no more injections, until either new symptoms arise or a continuation of those first observed indicates that the morbid action is not checked but is going forward, when further cleansing by aseptic injections should be practiced.

(To be concluded.)

Book Notices.

Medical Annals of Baltimore, from 1608 to 1880, including Events, Men, and Literature. To which is added a Subject-Index and Record of Public Services. By JOHN R. QUINAN, M. D., etc. Baltimore, 1884. Pp. 274.

At a special meeting of the Medical and Chirurgical Faculty of Maryland, held October 13, 1880, in commemoration of the founding of the city of Baltimore, the duty of writing the history of the medical men of the city during the preceding century and a half was assigned to the author of this volume.

So far as we are able to judge, the task has been carefully performed, and the medical history of the country has doubtless received a valuable addition through the publication of this volume.

Shakespeare as a Physician. Comprising every Word which in any way relates to Medicine, Surgery, or Obstetrics, found in the Complete Works of that Writer, with Criticisms and Comparison of the same with the Medical Thoughts of to-day. By J. PORTMAN CHESNEY, M. D., Ex-secretary, Medical Society of the State of Missouri, etc. Chicago, St. Louis, and Atlanta: J. H. Chambers & Co., 1884. Pp. 226.

This is certainly a unique, and we may add interesting, contribution to Shakespearean and medical literature as well.

It will decidedly repay a perusal.

The Parents' Medical Note-Book. Compiled by A. DUNBAR WALKER, M. D., C. M. London: H. K. Lewis, 1884. Pp. 26.

This little book is compiled for the purpose of enabling parents to keep a record of the diseases which their children pass through. The object is a good one, and useful deductions may be derived from such records.

BOOKS AND PAMPHLETS RECEIVED.

On Tumors of the Bladder; their Nature, Symptoms, and Surgical Treatment. Preceded by a Consideration of the Best Methods of Diagnosing all Forms of Vesical Disease, including Digital Exploration and its Results. With Numerous Illustrations. By Sir Henry Thompson, F. R. C. S., M. B. Lond., Surgeon Extraordinary to H. M. the King of the Belgians, etc. Philadelphia: Blakiston, Son & Co., 1884. Pp. 111.

Hand-book of the Diagnosis and Treatment of Skin Diseases. By Arthur Van Harlingen, M. D., Professor of Diseases of the Skin in the Philadelphia Polyclinic and College for Graduates in Medicine, etc. With Two Colored Plates. Philadelphia: P. Blakiston, Son & Co., 1884. Pp. xii-282.

Kefyr, kaukasisches Gährungsferment und Getränk aus Kuhmilch. Seine Geschichte, Literatur, Zubereitung, Zusammensetzung, sowie physiologische und therapeutische Bedeutung. Von Dr. W. Podwysotszki (Sohn). Aus dem Russischen nach der dritten Auflage übersetzt von Moritz Schulz, Arzt beim 114 kais. russ. Infanterieregiment. St. Petersburg: Carl Ricker, 1884. Pp. xi-78.

The Galvano-caustic Method in Nose and Throat. [Reprint from the "St. Louis Courier of Medicine."] A Case of Intrathoracic Aneurysm, with Special Comments on the Laryngeal Phenomena. [Reprint from the "Weekly Medical Review."] By J. C. Mulhall, M. D., St. Louis.

Report on Tuberculosis. By D. N. Kinsman, M. D., of Columbus, Ohio. [Reprint from the "Transactions of the Ohio State Medical Society."] 1884. Pp. [11]-1055.

The Huroan Element in Sex: being a Medical Inquiry into the relation of Sexual Physiology to Christian Morality. By Dr. Elizabeth Blackwell. [Second Edition, revised and enlarged. London: J. & A. Churchill, 1884. Pp. 9 to 58, inclusive.

Index-Catalogue of the Library of the Surgeon-General's Office, United States Army. Authors and Subjects. Vol. V. Flaccus—Bearth. Washington: Government Printing Office, 1884. Pp. [11]-1055.

A Practical Treatise on Fractures and Dislocations. By Frank Hastings Hamilton, A. B., A. M., M. D., LL. D., late Professor of Surgery in Bellevue Hospital Medical College, etc. Seventh American Edition, revised and improved. Illustrated with Three Hundred and Seventy-nine Woodcuts. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xxxi-1005.

London Water Supply. Report on the Composition and Quality of Daily Samples of Water supplied to London during the Year 1883. By William Crookes, F. R. S., William Odling, M. D., F. R. S., F. R. C. P., Professor of Chemistry in the University of Oxford, and C. Meymott Tidy, M. B., F. C. S., etc., Professor of Chemistry and of Forensic Medicine at London Hospitals, etc.

The Lock-Jaw of Infants (Trismus Nascentium), or Nine-Day Fits, Crying Spasms, etc. Its History, Cause, Prevention, and Cure. By J. F. Hartigan, M. D., Washington, D. C., Member of the American Medical Association, etc. New York: Bermingham & Company, 1884. Pp. 7-123. [Price, 75c.]

Remarks on the Pathology and Treatment of Tubal Nephritis. By James Barr, M. D., L. R. C. S. Edin., Physician to the Stanley Hospital, Liverpool, etc. Pp. 203-234. [Reprint from the "Liverpool Medico-Chirurgical Journal," July, 1883.]

'Report on the Causes and Mechanism of the Cardiac Impulse. By James Barr, M. D., etc. Pp. 1-40. [Reprinted for the Author from the "British Medical Journal," July 26, 1884.]

Announcement of the Regular Session of 1885 of the Hospital College of Medicine, Medical Department of Central University, Louisville, Ky.

Restriction and Prevention of Diphtheria. Document issued by the Michigan State Board of Health.

Restriction and Prevention of Scarlet Fever, etc. Document issued by the Michigan State Board of Health.

Laws of Michigan relating to the Public Health, in force September 8, 1883.

Transactions of the Michigan State Medical Society, for the Year 1883.

Transactions of the Medical Society of the State of California, for the Years 1883 and 1884.

Transactions of the Medical Society of the State of West Virginia, Seventeenth Annual Session, 1884.

London Water Supply. Report, etc., No. xliii.

Irritation of the Prostate. By R. Harvey Reed, Mansfield, O. [Reprint from the "Columbus Medical Journal."]

Cryptorchidism, with an Illustrative Case. By Robert W. Johnson, M. D. [Reprint from the "Transactions of the Medical and Chirurgical Faculty of Maryland."]

Poisoning by Cannabis Indica, etc. By A. B. Cook, A. M., M. D. [Reprint from the "American Practitioner."]

Cases of Interest. By W. H. Carmalt, M. D., New Haven. [Reprint from the "Proceedings of the Connecticut Medical Society."]

Suprapubic Lithotomy. By W. S. Tremaine, M. D., etc., Buffalo, N. Y.

Hospital Sunday and Hospital Saturday: their Origin, Progress, and Development; together with Suggestions for making both Funds more useful to the Hospitals. By Henry C. Burdett, Founder of the Home Hospitals Association for Paying Patients, etc. London: Kegan Paul, Trench & Co., 1884. Pp. 35. [Price, 6d.]

The Influence of Lung Retractivity in Pleurisy and Pneumothorax. By F. Donaldson, M. D., etc. [Reprint from the "Transactions of the Medical and Chirurgical Faculty of Maryland."]

A Periodical Painful Affection, etc. By R. Harvey Reed, M. D., Mansfield, O. [Reprint from the "Journal of the American Medical Association."]

Preventable Blindness. By Samuel Theobald, M. D., etc. [Reprint from the "Transactions of the Medical and Chirurgical Faculty of Maryland."]

Abdominal Surgery. Four Cases, with Comments. By Joseph Eastman, M. D., etc. [Reprint from the "Transactions of the Indiana State Medical Society."]

Later Antiseptics in Private Surgical Practice. By Dr. Powell, Edgar, Ont. [Reprint from the "Canadian Practitioner."]

NEW YORK, SATURDAY, OCTOBER 11, 1884.

THE AMERICAN GYNÆCOLOGICAL SOCIETY.

THE three days' session of the ninth annual meeting of the society, held in Chicago last week, may be said to have been experimental in one respect—namely, that the place of meeting, being situated nearly halfway across the continent from the Atlantic seaboard, was, in the opinion of some of the members, likely to prove the cause of a failure of the meeting to come up to the average in the interest of the proceedings. How completely this gloomy and thoroughly un-American forecast was at fault was realized by those of the members who were able to be present, and doubtless none were more pleasantly disappointed than some of those who had most positively predicted the untoward result we have alluded to. And we think our readers will appreciate the success of the meeting when we state that the three days were so fully taken up with the discussions that, of the eighteen papers set down on the programme, seven had to be read by title only. It is to be regretted, of course, that that very fact precluded any discussion of the interesting subjects with which those seven papers dealt; but the papers themselves will appear in the forthcoming volume of the "Transactions," and will then be up for discussion before a larger body—that of the profession in general.

Nor was the character of the work done one whit behind the standard. It may seem invidious to single out individual papers for special mention, but we can not forbear to allude to a few of those that were presented. Dr. Thomas's paper, for instance, valuable as it was, even considered as a mere contribution to the casuistics of extra-uterine pregnancy, seems noteworthy as conveying by all odds the most precise and rational exposition that has yet come to our knowledge of the respective scopes of electrical treatment and of laparotomy in the management of that appalling accident. Of Dr. Mundé's paper on vaginal hysterectomy, too, it must be said that it presented the merits of that operation so engagingly as to call forth from one of its moderate opponents the remark that its author was a most persuasive advocate; and certainly, considering that it was obviously a reply to Dr. Jackson's paper, read at the preceding annual meeting, the discussion it called forth was notably calm and judicial, while the opposing views expressed ought to save the society from being understood, as it seems to have been understood last year, to have given a quasi-authoritative indorsement to either the one or the other side of the question. Scarcely less remarkable were the same author's paper on the removal of fibrous growths during gestation and Dr. Palmer's admirable presentation of the subject of exploratory laparotomy, each of which brought out a satisfactory discussion, as will be seen by our report of the proceedings.

It is a matter for congratulation that the atmosphere of the meeting was not so overwhelmingly gynæcological, using the word in its restricted sense, as has often been the case. On most occasions heretofore this society and its congeners have appeared to be swayed by an overpowering temptation to bend all their energies to the consideration of the surgical diseases peculiar to women, to the exclusion of the parturient act, which, like the poor, we have always with us. That this was due to a temporary tendency—perhaps an infatuation—has for some time past been realized by those who practiced both branches of what ought really to be understood by the term gynæcology, and it is gratifying to observe that the turning-point seems to have been reached.

At no time during the year have we looked forward to the Chicago meeting with the slightest idea that it was likely to rank at all lower than those that had been held before. We had anticipated, indeed, that the attendance of members from the East would be relatively small, and so, to our shame be it said, it turned out—only three being present from New York, two from Boston, two from Baltimore, and one from Philadelphia. That it should be held to be a greater sacrifice, especially in these days of international congresses, for our eastern men to go to Chicago than for our western friends to make the pilgrimage year after year to our part of the country—in other words, that men should act as if it were farther from New York to Chicago than from Chicago to New York—is past our comprehension. Apart from the interest attaching to the meeting, it was well worth the journey in this instance, if only to look upon the wonderful city that Dr. Thomas, with his customary felicity of expression, characterized in his after-dinner speech as "the Empress of the West." But little, if at all, and that only for a time, does Chicago's professional importance lag behind her commercial supremacy, as our readers must have inferred from the reports we have published from time to time of the proceedings of the Chicago Medical Society.

It must be confessed that the attendance at the meeting, either of members or of spectators, was not large, but among those who were present by invitation there were several who, when we consider the degree to which they are immersed in the absorbing duties of practice, and the fact that a number of them came from great distances, gave the plainest testimony to the attractiveness of the occasion. That their number was not larger is to be explained, we are inclined to think, by the fact that the meeting took place later than usual, at a time when imperative college and hospital engagements had begun, rather than by the remoteness of the place of meeting. It is undoubtedly an important part of what is legitimately expected of special societies that their proceedings should be carried on in full view of the profession at large, and in the case of this particular society that consideration has been so fully recognized as to influence it, thus far, in its decision not to hold its meetings at watering-places; but whenever, as in this instance, a society of specialists finds its members gathered together with comparatively few spectators, the discussions are apt to be somewhat freer than might otherwise be the case. This was observable,

we think, in the case of the Chicago meeting, and it must be accounted a compensation for the thin attendance.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 7, 1884:

DISEASES.	Week ending Sept. 30.		Week ending Oct. 7.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	2	0	1	1
Typhoid Fever.....	57	12	48	12
Scarlet Fever.....	25	2	36	3
Cerebro-spinal meningitis. . .	3	2	2	3
Measles	17	4	19	5
Diphtheria.....	28	12	40	19

Death of Dr. David F. Fetter.—On Thursday, the 2d inst., Dr. Fetter died at his residence, in West Thirty-fourth Street. He took his medical degree in Philadelphia in 1853, and afterward was graduated from the College of Physicians and Surgeons, of this city. He was a member of the Medical Society of the County of New York.

Diphtheria, according to a press dispatch, is unusually prevalent in various parts of Canada at the present time.

Contagious Pleuro-pneumonia on Long Island.—A number of cases of this disease are reported to have been found during the past week at Long Island City and Blissville by Dr. Rowland and Dr. Hawk, who are investigating the condition of the cows in that locality, under instructions from the Department of Agriculture. It is said that the milk furnished by some of the cows that have been found to be diseased was still being sent to the New York market.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 23, 1884, to October 4, 1884:*

BENTLEY, EDWIN, Major and Surgeon. Granted two months' leave of absence, with permission to apply for two months' extension, to take effect upon assignment to duty in Department of Texas of Surgeon F. L. Town. S. O. 121, Headquarters Division of the Missouri, September 30, 1884.

BARTHOLOMEW, JOHN H., Captain and Assistant Surgeon. Assigned to duty at Fort Ringgold, Texas, as Post Surgeon. Par. 5, S. O. 129, Headquarters Department of Texas, September 25, 1884.

CRAMPTON, L. W., Captain and Assistant Surgeon. Granted leave of absence for one month and ten days. S. O. 60, Headquarters Division of the Atlantic, October 2, 1884.

GIBSON, R. J., First Lieutenant and Assistant Surgeon. Assigned to duty as Post Surgeon, Fort Winfield Scott, California, relieving Assistant Surgeon A. S. Polhemus.

POLHEMUS, A. S., First Lieutenant and Assistant Surgeon. Upon being relieved, to report to commanding officer, Fort McDermitt, Nevada, for duty as Post Surgeon.

WHITE, R. H., Captain and Assistant Surgeon. To report to commanding officer, Angel Island, California, as Post Surgeon, relieving Assistant Surgeon C. K. Winne.

WINNE, C. K., Captain and Assistant Surgeon. Upon being relieved, to report to commanding officer, Benicia Barracks, California, for duty as Post Surgeon, relieving Surgeon C. O. Byrne. Par. 1, S. O. 115, Headquarters Department of California, September 23, 1884.

EVERETT, EDWARD, First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, with permission to leave the limits of the department. S. O. 145, Headquarters Department of the Columbia, September 24, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending October 4, 1884:*

STEWART, HENRY, Surgeon. Granted leave of absence for one year, with permission to leave the United States, October 15, 1884.

EDGAR, JOHN M., Passed Assistant Surgeon. Detached from the Nantucket and placed on waiting orders, September 29, 1884.

HARMON, G. E. H., Passed Assistant Surgeon. Ordered to the Naval Academy, September 30, 1884.

BERTOLETTE, D. N., Passed Assistant Surgeon. Ordered from the Naval Academy to the Dolphin, October 4, 1884.

ROGERS, BENJAMIN F., Passed Assistant Surgeon. Ordered to the Naval Academy, September 30, 1884.

COOKE, GEORGE H., Surgeon. Relieved from the Naval Academy and placed on waiting orders, October 2, 1884.

WHITING, ROBERT, Passed Assistant Surgeon. Relieved from the Naval Academy and placed on waiting orders, October 4, 1884.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service—July 1, 1884, to September 30, 1884.*

BAILHACHE, P. H., Surgeon. To proceed to Delaware Breakwater Quarantine Station as inspector, September 10, 1884. To investigate reported pollution of Potomac River water supply, September 20, 1884.

MILLER, T. W., Surgeon. Granted leave of absence for fourteen days, July 10, 1884. Detailed as president Board of Examiners, September 2, 1884.

WYMAN, WALTER, Surgeon. Detailed as member Board of Examiners, September 2, 1884.

LONG, W. H., Surgeon. Granted leave of absence for twenty days, July 30, 1884.

PURVIANCE, GEORGE, Surgeon. Detailed as recorder Board of Examiners, September 2, 1884.

STONER, G. W., Passed Assistant Surgeon. To proceed to Lewes, Del. (Delaware Breakwater), as inspector, July 25, 1884. To act as quarantine officer at Delaware Breakwater, July 31, 1884.

FISHER, J. C., Passed Assistant Surgeon. Granted leave of absence for thirty days, August 21, 1884.

GOLDSBOROUGH, C. B., Passed Assistant Surgeon. Granted leave of absence for thirty days, July 12, 1884. Leave of absence extended thirty days on surgeon's certificate of disability, August 11, 1884. Leave of absence extended thirty days without pay, September 11, 1884.

HEATH, W. H., Passed Assistant Surgeon. Granted leave of absence for thirty days, September 8, 1884.

GUITERAS, JOHN, Passed Assistant Surgeon. Granted leave of absence for thirty days, September 24, 1884.

BANKS, C. E., Passed Assistant Surgeon. Granted leave of absence for thirty days, August 27, 1884.

BENNETT, P. H., Assistant Surgeon. To proceed to Buffalo, N. Y., for temporary duty, September 19, 1884.

GLENNAN, A. H., Assistant Surgeon. To proceed to Mobile, Ala., for temporary duty, July 7, 1884.

Resignation.

FISHER, J. C., Passed Assistant Surgeon. Resignation accepted by the Secretary of the Treasury, to take effect September 30, 1884. August 21, 1884.

Society Meetings for the Coming Week:

- MONDAY, October 13th:** New York Ophthalmological Society (private); New York Medico-Historical Society (private).
- TUESDAY, October 14th:** American Public Health Association (St. Louis—first day); New York Medical Union (private); Harlem Medical Association of the City of New York; New York Surgical Society; Bergen County, N. J., Medical Society (Hackensack); Cumberland County, N. J., Medical Society (semi-annual); Newark, N. J., Medical Association (private); Trenton, N. J., Medical Association (private); Litchfield County, Conn., Medical Society (annual).
- WEDNESDAY, October 15th:** American Public Health Association (second day); Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark).
- THURSDAY, October 16th:** American Public Health Association (third day); New York Academy of Medicine (The Therapeutical Effects of the Internal Administration of Hot Water in the Treatment of Nervous Diseases, by Ambrose L. Ranney, M. D.).
- FRIDAY, October 17th:** American Public Health Association (fourth day).

Letters to the Editor.

PLASTER-OF-PARIS JACKETS FOR SPINAL DEFORMITIES.

DEXTER, IOWA, September 10, 1884.

To the Editor of the New York Medical Journal:

SIR: If others of your readers have had a similar experience to my own in the matter of applying plaster-of-Paris jackets for spinal deformities, they will be glad to receive light on the means of persuading the plaster to "set." Having lately had occasion to attempt a job of this kind, I failed utterly in the first two trials, as the plaster obstinately refused to "set," although I had a fresh article of the best dental plaster-of-Paris. Then I went to experimenting, and, after trying a number of different chemicals dissolved in the water in which I soaked my bandages, I found that chlorate of potassium thus used (about two ounces to one gallon and a half of water) answered the purpose nicely, the only trouble being that it is necessary to work very rapidly, or the plaster hardens too quickly.

M. G. SLOAN.

Proceedings of Societies.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.*Meeting of September 25, 1884.*

The President, Dr. JAMES TYSON, in the chair.

A Phantom Brain was shown by Dr. GUY HINSDALE. It was of colossal size, and was intended to exhibit the course of the fibers and their relation to the several nuclei and to the spinal cord. The preparation had been recently purchased for the Mutter Museum of the College of Physicians, and was constructed by Buechi, of Berne, Switzerland, under the supervision of Professor Aebly. The height was 125 cm. and the width 70 cm. The cortex was dotted over with numerous corks, 2 cm. long, which were distributed in systematic order. The basal nuclei, of a much larger size, were seen in their appro-

priate places. The spinal cord, made up of ganglia and columns of wires of different colors, was represented throughout a portion of the cervical region. These columns of the cord, of different colors to distinguish their function, led to their appropriate ganglia, of corresponding color, or to the areas in the cortex which were marked by similarly colored corks. Taking, first, the anterior and lateral columns of the cord, painted red, the motor fibers could be traced to the anterior and lower portion of the medulla, where they decussated, through the pons, to the internal capsule, where, between the caudate nucleus of the corpus striatum and the optic thalamus, they radiated to the cortex. They were seen to come chiefly from the convolutions about the fissure of Rolando. From a point where red balls were seen a red motor fiber descended to the anterior or lateral columns. It would be seen that the column of Türeck, or the direct pyramidal tract, was in relation with the posterior part of the lateral column of the opposite side. As regarded the exact localization of the sensory and motor tracts of the spinal cord, there was still some discrepancy of opinion. Professor Ferrier stated that the antero-lateral columns were usually regarded as the chief motor paths, but quoted the recent and careful experiments of Ludwig and Woroschiloff (1874), who placed the motor paths in the lateral columns only. The anterior columns (of Türeck) were regarded more as commissural connections between the motor nerves and adjacent segments, and not at least as the direct paths of motor impulses proceeding from the brain. Tracing the fibers of the posterior columns, colored blue, they were represented as wholly decussating in the medulla forming the posterior third of the internal capsule and passing to the corpora quadrigemina and optic thalami, also colored blue, which were the great centers of sensation. The external portion of the lateral columns, colored green, were seen to lead to the cerebellum, decussating near its superior surface. The yellow fibers of the model placed the basal nuclei in communication with the cortex; the white fibers constituting the corpus callosum were purely commissural. The columns of the cord, as represented in the model, corresponded precisely with the arrangement given by Flechsig and endorsed by Charcot and Hammond. Ludwig and Woroschiloff* argued that a vicarious interchange of function potentially existed between different parts of the cord.

A Case of Infantile Mollities Ossium was presented by Dr. CHARLES MEGGS WILSON, for Mr. CLINTON DENT, of St. George's Hospital, London. The following history had been furnished by Mr. Dent: "This specimen shows the inner vertical half of the right femur of a child aged sixteen months. There is a pseudo-fracture of the bone. The medullary canal is filled up, and a considerable deposit of enveloping callus maintains the fragments in apposition. The entire bone is unnaturally soft, and in the recent state showed this peculiarity still more strongly. The bone was removed post mortem from the body of a feeble, ill-nourished child. No history of syphilis could be got from the parents, and the child showed no evidence of congenital syphilis. Some of the ordinary symptoms of rickets were observable, e. g., bending of the ribs, general tenderness, enlargement of the wrists, etc. No symptoms of scurvy were present. It was evident that there was much more than rickets in the condition. When the child was first admitted to the hospital there were pseudo-fractures of the right humerus and left tibia, besides the fracture of the right femur. The humerus, which was bent at a right angle, was forcibly straightened. It bent like a bar of soft metal, and remained in its new position. It was, however, put in a light pasteboard splint. Subsequently, with the removal of the splint, the bone again gradually bent and was again forcibly

* Ferrier, "Functions of the Brain," London, 1876, p. 5.

straightened. While in the hospital, under observation, the femora became affected in the usual place—i. e., a little below the trochanters. Some swelling and tenderness were noticed, and then, although the child was kept constantly in bed, the bones became bent; ultimately, in about ten days, the pseudo-fractures became complete. Great improvement of the general health, as evidenced by rapid increase of weight, resulted from the treatment by rest, good diet, and cod-liver oil. The child finally died from an attack of whooping-cough, after having been under observation a few weeks.¹¹

This was a very rare form of bone disease, Dr. Wilson remarked, especially in the young. It was seen occasionally in England—never with us. The pathological changes seemed to be of a retrograde character. Sometimes lipomatosis took place; sometimes there was a metamorphosis, first into cartilage and then into embryonic tissue. This specimen showed, in different portions, both changes. The disease was attended with marked fatality. In this specimen the cortical substance was attenuated, and the medullary cavity was enormously enlarged. The bone seemed deficient in lime-salts. Some authorities believed that the lactic acid found in the chemical analysis of such bones was accountable for this. This fact was mentioned in order to elicit discussion. Other observers had found enormous quantities of oxalate of lime in the urine of patients with malacostron bones. One curious fact was the effort which nature made to repair the fractures, as shown in this specimen. This callus seemed deficient in inorganic matter, and eventually became reabsorbed. Syphilis, scrofula, and scorbutus had all been assigned as causes of the affection. Most authorities denied the existence of the disease in children, assigned it to middle life, and spoke of it as being lighted up or aggravated in women by pregnancy.

AMERICAN GYNÆCOLOGICAL SOCIETY.

Ninth Annual Meeting, held in Chicago, Tuesday, Wednesday, and Thursday, September 30, and October 1 and 2, 1884.

Tuesday's Proceedings.

THE meeting was called to order by the President, Dr. ALBERT H. SMITH, of Philadelphia.

THE Address of Welcome was read by Dr. WILLIAM H. BTFORD, of Chicago. Many of the members of the society, he said, now found themselves in Chicago for the first time; others had been there many times in the past. As to the former, the fame of their good works had come before them; the latter were known in person as well as in renown. He and his colleagues of the Committee of Arrangements desired to give all present such a welcome as would make them feel entirely at home. He expressed the hope that the desire to see the city—a place that but a few years ago was a village on the outskirts of civilization, but now exerted a vast influence in the commerce of the world—would detain many of the members beyond the time occupied by the meeting. He then alluded to the loss that the profession of medicine, and gynecologists in particular, had sustained in the death of that leader, the late Dr. Marion Sims.

Moot Points in regard to Inversion of the Uterus was the title of the first paper, read by Dr. JOHN C. REEVE, of Dayton, Ohio. It dealt with the causes and the mechanism of the lesion, and the medico-legal importance that sometimes attached to them. In the vast majority of instances, as was conceded by all writers, inversion of the uterus took place only as an accident of delivery or as the result of the sudden expulsion of a polypus, but very high authorities had admitted that hydrometra and hæmatometra might lead to its occurrence, although the sup-

position had not been proved by actual cases. In regard to such a subject, however—a rare accident, happening oftener in cases attended by midwives and other ignorant persons than under competent observation, and calculated, by the suddenness of its occurrence and by its appalling nature, to interfere with cool judgment—it was allowable to reason in relation to certain points in the absence of precise data. The first question he would discuss was, therefore, *Could inversion of the uterus occur wholly independently of pregnancy or of a polypus?* It was evident that hydatids furnished the conditions admitted to be requisite, namely, distension and sudden emptying of the organ; but he would exclude that affection also from his question. With a healthy uterus, probably there could be no inversion independently of the conditions mentioned; but it had first been affirmed by Puzos that certain pathological changes in the organ might favor its occurrence. Mme. Boivin had coincided in this opinion, and Tyler Smith had maintained that inversion had actually happened from such a cause, the particular occasion being spasmodic action of the uterus coming on in the course of long-continued menorrhagia. On the other hand, Duncan and West had denied the possibility of such a thing, the former arguing that the uterine wall was so thick and firm that it could not be indented. This argument, however, ignored pathological conditions of the organ, and therefore was irrelevant. Duncan himself had shown that an enlarged and softened state of the uterus was not rare in connection with disease. Such changes need not be very marked to produce the result, as was shown by the occurrence of inversion after abortion, of which there were many cases on record. The condition termed by Rigby the "squatty uterus" seemed to have been observed by Mme. Boivin, and, in our own times, had been well described by Dr. Isaac E. Taylor, of New York. But, to come to facts, there were three cases which seemed to settle the matter; one related by Baudelocque, one by Boyer, and one by Dr. T. Gailard Thomas, of New York. The latter case was that of a young woman who had had one child, seven or eight years before, but had not been known to have any uterine disease. She made a violent effort in a game of ten-pins, and suddenly felt something give way within her, accompanied by intense pain. The family physician made a vaginal examination and found a protrusion into the vagina, which he took to be a polypus that had suddenly been expelled from the uterus. The late Dr. Willard Parker, who was called in consultation, coincided in this diagnosis, and removed the supposed polypus, but found at once that he had removed the uterus, which had suddenly been inverted. The patient recovered.

The next question was, *Did inversion of the uterus always begin at the fundus, or did it not sometimes begin at the cervix?* Most writers had denied the possibility of inversion originating by a rolling out at the cervix, while some, like Dr. Thomas, had merely stated that its occurrence was not proved. Tyler Smith had been credited with having upheld the doctrine, but he (Dr. Reeve) had not been able to find that author's enunciation of it. There was strong analogical evidence in its favor, the process being held to be like that by which a prolapse of the rectum or an intussusception was produced. The organ must have become soft and flabby to admit of it, however. In proof of the possibility, reference was made to an essay by Dr. Isaac E. Taylor, who had given three cases, one of which had come under his own observation. On the whole, the evidence seemed to be strong enough to warrant the affirmation that inversion might begin at the cervix.

The next question was, *Did puerperal inversion of the uterus ever occur except at or immediately after delivery?* Upon this question turned that of the responsibility of the accoucheur, who could not be held blameless if he overlooked an accident usually

so marked in its symptoms, provided it were established that it always took place at a time when he was or should have been present. The question, therefore, was one of medico-legal importance, and in that connection reference was made to a case that happened in Chicago a number of years ago, in which a physician took legal proceedings against the patient's husband, who had repeatedly charged him with incompetence in the management of the case, and had coupled abuse with his criticism. The suit went against the physician, but, turning as it did upon the question now under consideration, it was doubtful if the decision was a just one. When there was nothing at the time of labor, or during the usual period of attendance, to show that anything was wrong, but symptoms of inversion came on suddenly afterward, could it be held, nevertheless, that the accident had really occurred at the time of the confinement? Such instances were not rare, and in one case a year had elapsed between the labor and the recognition of the inversion, although there had been profuse and repeated hemorrhages in the interval. Under such circumstances, it was incumbent upon the practitioner to endeavor to detect the presence of inversion. Several cases were cited to show the possibility of puerperal inversion coming on after the lapse of a considerable length of time, and the frequency with which secondary hemorrhage and relaxation of the uterus were observed was spoken of as supporting the idea.

The fourth question was, *Could inversion take place without symptoms sufficient to attract attention or to indicate that anything had gone wrong?* Striking as the symptoms usually were, several cases were cited to sustain an affirmative answer to this question, and it was therefore concluded that it must be so answered.

Dr. JOHN SCOTT, of San Francisco, had met with two instances that seemed to have a bearing on the questions raised in the paper. In one of them the patient was attended in her confinement by a homeopathic physician, who, according to her account, seemed to be in some haste to remove the placenta. The history indicated that the inversion took place at the time the placenta was extracted, but for a number of weeks leucorrhœa and pain in the back were the only symptoms, the primary recurrent hemorrhages having subsided. At the time of her weaning the child, however, eight months after its birth, the hemorrhage recurred. When Dr. Scott reduced the inversion, an operation that took some twenty minutes, he felt that some of the circular fibers of the uterus gave way, and he found that the organ remained flaccid. At the next menstrual period there was a return of the hemorrhage, and another at the second period. On the latter occasion, having found the bleeding difficult to control, he introduced two silver sutures and drew the womb together. This stopped the hemorrhage, but it was followed by a sharp attack of cellulitis.

Dr. WILLIAM H. BYFORD, of Chicago, had seen nine or ten cases of inversion of the uterus, and one of them had occurred in his own practice. A healthy young woman gave birth to her second child, and there was nothing unusual about the labor. He did not examine by the vagina, but he was perfectly satisfied, from thorough abdominal palpation, that the uterus was of proper size and shape. There was no hemorrhage, and everything appeared right. Some weeks afterward moderate hemorrhage occurred, at the time of weaning the child, and, as Dr. Byford happened to be out of town, another practitioner was called in, and detected an inversion, which was the occasion of great astonishment to Dr. Byford.

Dr. B. BERNARD BROWNE, of Baltimore, related a case in which the symptoms did not come on until the sixth week, when pain and syncope suddenly occurred. In that case it was probable that the inversion began toward the cervix. The attend-

ance had been competent. He alluded to the difficulty sometimes encountered in producing temporary inversion to facilitate the removal of tumors.

Dr. ALEXANDER DUNLAP, of Springfield, O., related a case in which hemorrhage continued after labor, but the os uteri was found closed, and the inversion was not detected until some months later, although examinations were made from time to time. In this case the inversion was probably partial for a time, and began at the fundus.

Dr. EDWARD W. SAWYER, of Chicago, alluded to unusual distension of the uterus as a cause of inversion, and related the history of a case of hydramnios in which, after the removal of the placenta, the proper shape of the uterus was maintained, but the fundus remained at a higher level than natural. The flow of liquor amni had been so enormous that he thought it necessary to have the bedclothing changed at once, and undertook to attend to it himself, having called upon the husband to hold the uterus. While this was going on, occupying perhaps ten minutes, profuse hemorrhage began, and it was found that the fundus could not be felt. Ergot was given at once, on account of the hemorrhage. The fundus was now felt bulging through the os uteri, and all his efforts to replace it failed, owing to the tonic contraction that had been set up by the ergot. The patient went into a state of collapse, and died in three hours. The site of the placental implantation, in the right horn of the uterus, was found to be four times as thick as the rest of the organ, so that it seemed as if the fundus might have fallen in by the mere force of gravitation.

Dr. HENRY P. C. WILSON, of Baltimore, remarked, in regard to the question of the lapse of time between labor and the occurrence of inversion, that it was rather the state of the uterus than the time in itself that would favor the accident, especially anything that retarded involution, such as hemorrhage, mental strain, or over-exertion.

Dr. WILLIAM T. HOWARD, of Baltimore, related several cases of inversion that had come under his observation.

Foreign Bodies in the Abdomen after Laparotomy.—Dr. HENRY P. C. WILSON, of Baltimore, read a paper with this title. He had been led to think that foreign bodies, such as sponges and small instruments, left in the abdominal cavity after laparotomy, were much more frequently the cause of death than was generally supposed. Undoubtedly there were many cases that were never published, partly because of their damaging character, and partly because, as post-mortems were not always made, the presence of the foreign body was sometimes never discovered. On this account he had not been able to collect a large array of cases; still he had received accounts of quite a number, including several that had been reported to him verbally since he left home to attend the meeting. After giving the leading facts in these cases, he read a detailed history of a remarkable case that had happened in his own practice. In that case the foreign body was a portion of sponge, and its presence in the abdomen was not suspected until months after the operation. Ovariectomy was performed on a patient who was five months advanced in gestation, and miscarriage took place on the eighteenth day. After more than five months, during a great portion of which time the patient continued to suffer from symptoms referable to the formation of abscesses, a bit of sponge was found presenting one day when an abscess was opened. Its removal with a forceps was followed by free hemorrhage, so that, although it was evident that more sponge was still in the abdomen, it was judged best to effect its removal gradually, and that process occupied a number of weeks, several pieces being removed, amounting altogether to a mass nearly as large as a hen's egg. The patient then went on rapidly to complete recovery. In that case the sponges had been counted, not by a

nurse, but by his own son, at the time of the operation, and he could not account for the mistake except by the supposition that a piece had become detached from a large sponge during the process of sponging. For the prevention of such accidents, he would make the following suggestions: The operator should do his own sponging; sponges and instruments should be employed in no greater number than was absolutely necessary, and they should not be too small; it should be made the specified duty of one of the assistants to see that no foreign bodies were left in the abdomen; the assistants should be as few as possible, one being better than three, and none better than five.

Dr. T. GAILLARD THOMAS, of New York, thought that such a paper was one that had been decidedly called for for a long time. In over four hundred cases of laparotomy, the accident had occurred to him only once. In that case he had not taken even a single sponge into his own hand, and had had only one assistant, Dr. James B. Hunter, whose skill and carefulness were well known; and there had been only one sponge used at all. At the post-mortem examination, a small piece of sponge was found in the abdominal cavity, and evidently it had become detached during the process of sponging. There were many cases, he thought, in which the operator could not do all the sponging himself, as his hands were fully occupied in other matters, and he was forced to assign a portion of it to an assistant. It was useless to depend on a nurse to count the sponges; if too few were found at the close of the operation, there was a great temptation to her to infer and to assert that the full complement had not been present at the start. As a matter of precaution, it was now his practice to attach a tape, five or six inches in length, to each sponge, and this was to be kept hanging out from the wound whenever the sponge was introduced. The length of time for which hæmostatic forceps were kept applied to vessels should be shortened, and they should not be suffered to disappear from view even for an instant. Incidentally, Dr. Thomas stated that it had come to be the practice at the Woman's Hospital to use chloroform instead of ether in case the patient was suffering from renal disease, for it had been observed there (first by Dr. Emmet, he thought) that patients so affected were liable to suffer from suppression of urine after the use of ether.

Dr. A. REEVES JACKSON, of Chicago, knew of three instances in which foreign bodies had been found in the abdomen after laparotomy performed in that city, but none of them had happened in his own practice. It was his habit to have a written list made of all the sponges and instruments in the room at the time of the operation, and, on its completion, he checked them off from the list himself. It was a standing order, too, that sponges were never to be torn.

Dr. DUNLAP had been surprised at the facts stated in the paper and at the minute precautions which had been thought necessary. For his own part, he allowed no one to hand him the instruments, or to do the sponging; he attended to those matters himself. He used very few sponges, and those were very large. Consequently, he had never had any fear that he had left any foreign body in the abdomen.

Dr. HOWARD spoke of the admirable method employed in the Samaritan Hospital in London: fifteen sponges were provided, and these were checked off by two nurses when an operation had been completed. He alluded to two cases that had occurred there before this system was adopted. In one of them the abdomen was opened and the sponge removed, and the patient recovered; in the other, the sponge could not be found when the wound was opened, and death resulted.

Dr. GEORGE J. ENGELMANN, of St. Louis, could add one to the list of cases contained in the paper, and it was one of which he had declined to write when Dr. Wilson had asked him for an account of any cases he might know of. It had occurred in

his own practice, but he did not feel that he was responsible for the occurrence, for it was due to the meddling of a distinguished gynecologist from the East, who had been invited to be present, and who became so interested in the operation that he persisted in sponging, although remonstrated with more than once. The patient did well for two days, and then passed into a state of depression, with melancholia, and died. At the post-mortem a sponge was found high in the abdomen, beneath the omentum. There was no inflammation about it, only a little injection.

Dr. PAUL F. MUNDÉ, of New York, thought it important that the sponges should be in such condition that they would not readily tear in their use, and that when they were to be made smaller they should be cut rather than torn. In removing the large flat sponges with forceps, there was danger of detaching pieces if the sponges were not of good quality.

Dr. WILLIAM H. BAKER, of Boston, thought that not only those appliances that were simply used at the time, but also those substances that were to remain, such as sutures and ligatures, should be selected with great care.

Dr. WILSON was much pleased with the device mentioned by Dr. Thomas, and was inclined to make use of it in the future. Where a large incision had been made it was practicable to use only large sponges, but he could not admit that small sponges were to be avoided altogether.

Abdominal Section; its Value and Range of Application, was the title of a paper read by Dr. C. D. PALMER, of Cincinnati. Although the difficulties met with in the diagnosis of pelvic and abdominal tumors were no greater than pertained to those of the other great divisions of the body, we had in exploratory abdominal section a means of meeting them that could not be applied elsewhere. While, with proper precautions, it was scarcely more dangerous than tapping, it was incomparably superior in enabling us to ascertain the real state of the parts. Observers were not agreed as to the precise risk attending the operation of tapping, and he would not say that it never ought to be done, but he was convinced that it was highly dangerous in many instances, and that it should generally be avoided. The plan of tapping parovarian cysts and ovarian monoecysts once before proceeding to their removal was not very likely to prove curative, and positive reliance could not be put on the examination of the fluid withdrawn. The danger of an exploratory laparotomy, he thought, depended on the length of the incision and on the amount of handling to which the contents of the abdomen were subjected. Nevertheless, a small incision might prove fatal. Much depended on the patient's constitutional condition; if she had cancer, the operation was highly dangerous. Of five cases of cancerous disease in which he had done it to ascertain the presence of cancer, four had proved fatal in from three to thirty days; the other patient was still living, after the lapse of sixteen months. Where the vitality was not depreciated, the operation was practically free from danger in the cases that seemed reasonably to require it, although the danger of an incomplete ovariectomy was greater than that of a completed ovariectomy. In a certain sense, every laparotomy was exploratory, for we could never be positive at the outset as to what state of things we should find. Except under the stress of necessity, however, the operation should not be done by the inexperienced, for it was far more dangerous in their hands than in those of men who were frequently called upon to perform it. When it was decided upon, it should be done early, as there was danger in postponement. The incision should be made small at first, and could be enlarged if necessary. As to the cases in which the procedure was likely to be called for, they included some ovarian tumors with complications; certain interstitial and subperitoneal fibrous

tumors of the uterus, chiefly to settle the question between oophorectomy and hysterectomy; certain cases of acute or chronic peritonitis in which septicæmia was threatened; cases of intestinal obstruction; some cases of chronic pelvic abscess; extra-uterine pregnancy after the fourth month (early in the interstitial and tubal varieties—immediately in the abdominal form, without waiting for threatening symptoms). No doubt the operation was liable to abuse, but to a great extent it ought to supersede tapping.

Dr. ENGELMANN thought it was done too little in this country. It should not be too strictly a means of diagnosis, but often might prove the first step in a curative operation. He referred to three cases in which he had felt obliged to close the incision in consequence of the unfavorable conditions found. It was less dangerous than tapping, and far more satisfactory.

Dr. DUNLAP had had no experience with it; wherever he had been in doubt, it had been in cases where the patients' condition was such that an incision would have been unwarrantable.

Dr. MUNDE thought it was too much the habit to make a large incision at first in doubtful cases, so that the operator felt obliged to go on. Exploratory incision was rather a safe procedure, perhaps safer than tapping. In cases of pelvic abscess he would hardly call the incision exploratory.

Dr. WILSON referred to a case of hydramnios in which the procedure had saved him from puncturing the uterus by tapping. The diagnosis had been uncertain, but, when it was once made out, he did not hesitate to bring on labor, and the patient, although she had been at the point of death, did well.

Dr. R. B. MAURY, of Memphis, had resorted to the measure twice. In one of the cases there was supposed to be a multilocular ovarian cyst, and it was a question whether there was not a coil of intestine adherent to its anterior surface. This was found to be the case, and it was found also that the adhesion did not admit of being broken up, and, moreover, that the cyst was situated within the mesentery. The incision was closed, and the patient lived fifteen months. In the other case, one of uterine myoma, the question was with reference to the feasibility of removing the ovaries. This was found to be impracticable, the incision was closed, and the patient recovered.

Dr. A. REEVES JACKSON, of Chicago, inquired what the risk was when the operation was done for abscess.

Dr. DUNLAP had had one case of the sort referred to by Dr. JACKSON, in a male patient, in which he suspected abscess, although several other diagnoses had been made. He made an incision, not strictly exploratory, and was successful in restoring a chronic invalid to health.

Dr. SCOTT referred to a case that he had had, in the Woman's Hospital of the State of California, in which there was extensive suppuration in the broad ligament after labor, with an opening into the intestinal canal. He called a consultation of the staff, and proposed to perform an exploratory laparotomy, but his judgment was not concurred in at the time, and the operation was postponed until a later period, when the consent of his associates was given, the patient having in the mean time become septicæmic. There was decided improvement within four days, the opening into the intestine closed, and the patient recovered. In another case of obscure abscess, which had been opened through the vagina, but without relief, on abdominal incision the Fallopian tube was found to be the primary seat of suppuration. This was incised, but it was found impracticable to stitch the edges of the incision to the lips of the abdominal wound, drainage could not be carried out satisfactorily, and the patient died.

Dr. PALMER emphasized the exception he had referred to, that of malignant disease, in which cases the patients would

generally die in from three to ten days after the operation. He then referred to several cases in which tapping would manifestly have been of no avail to establish a diagnosis, but in which an incision only large enough to admit the left little finger gave all the information that was needed. In cases of pelvic abscess with long, tortuous tracts, where there were difficulties attending an opening from below, or where no fluctuation could be detected, an exploratory laparotomy was the one thing to be done.

Dr. ENGELMANN referred to cases of malignant disease in which it had proved harmless.

Dr. PALMER rejoined that, so far as that matter was concerned, his statements had been founded simply on his own experience.

Cervical Fibroids as a Cause of Dystocia, and their Removal by Vaginal Enucleation, was the title of the next paper, read at the afternoon session, by Dr. PAUL F. MUNDE, of New York. The author showed a tumor, weighing upward of three pounds, which he had removed from the cervix by enucleation. The circumstances of the case were these: The presence of the growth was ascertained a number of weeks before the time at which the patient expected to be delivered, but it was decided to postpone interference until the time of labor, mainly on the strength of a case in which Schröder had dealt with a large fibrous tumor successfully at term, although the tumor was not so large as in the case now referred to. Labor came on prematurely, however, and Dr. Munde found himself compelled to choose between the removal of the tumor and the performance of the Cæsarean operation. He decided upon enucleation, and found it comparatively easy of performance. He would not have felt like undertaking it without the spoon-saw, but it turned out that he had to use that instrument but very little. The author then gave a *résumé* of the literature of the subject, by which it appeared that enucleation gave better results than the Cæsarean operation. It was the common opinion that only small tumors could be treated successfully in this way, and a distinct statement to that effect had lately been made by Playfair, at a meeting of the Obstetrical Society of London, but it had been controverted by Braxton Hicks, and the case related in the paper went to confirm the opinion expressed by the latter gentleman.

The discussion on Dr. Munde's paper was postponed until the next day.

Wednesday's Proceedings.

The President being unable to preside, owing to illness, Dr. BYFORD occupied the chair.

The discussion on Dr. Munde's paper being in order, Dr. EDWARD W. JENES, of Detroit, related a case that had happened in his practice, in which a small fibroid was removed without difficulty, partly by enucleation and partly by excision, and in which the patient had done well. As a general thing, he would prefer enucleation to the Cæsarean operation in such cases.

Dr. WILSON called attention to the greater ease with which tumors could be so treated when situated in the cervical wall than when they sprang from the body of the organ.

Dr. BYFORD said that in the cases he had met with he had invariably postponed interference until the time of labor. To operate early was to run the risk of bringing on miscarriage; moreover, such tumors, even if interstitial, were often so pushed out before the head at the time of labor that they interfered but very little with the delivery. Sometimes, too, this pushing-out process so crushed the tumor as to facilitate its enucleation.

Dr. DUNLAP could not speak from personal experience in such cases, but he would call attention to the pedunculated state of the tumor in Dr. Munde's case—a condition that would decidedly facilitate its removal as compared with sessile and sub-

peritoneal tumors. However, he would try enucleation in almost any case.

Dr. ELY VAN DE WARKER, of Syracuse, had encountered one case in point, to which he had been called in consultation. The tumor was seated in the posterior cervical wall, and occupied a large part of the pelvic cavity. He proposed enucleation, but was overruled, and the Cæsarean operation was performed. The mother died of shock, and the post-mortem examination showed the practicability of enucleation.

Dr. THADDEUS A. REAMY, of Cincinnati, had seen but one case, in consultation. The tumor, which was situated in the posterior wall, was not detected before labor came on. It then presented at the os uteri, and there was no distinct pedicle. He incised the capsule and enucleated the tumor, and the patient did well. As a rule, he would wait until labor set in—for two reasons, besides those that had been mentioned by Dr. Byford: 1. Enucleation would be easier then, on account of the dilatation of the cervix, whereby the danger of using tents was avoided. 2. He thought that at the time of labor there was less rather than more risk of septiciæmia from such an operation.

Dr. MUNDÉ said that the point he had wished to make was, that enucleation was comparatively easy, even when the growth extended up somewhat into the body of the uterus, but, of course, it was easier at the time of labor. As to the time for the operation, he thought that it would vary with the nature of the individual case. Where a tumor was growing rapidly, he would operate early, and enucleation should always be the first procedure tried. It would be much facilitated by an efficient tracile instrument.

A Mediæval Instrument for preventing Coitus.—Dr. THOMAS showed a relic of the Middle Ages, in the shape of a contrivance for preventing women from indulging in intercourse. It had lately been given him by a friend, by whom it had been found in the bottom of one of a number of trunks that constituted, with the odds and ends which made up their contents, the remnant of an estate in Europe that he had been called upon to take charge of. The apparatus resembled the well-known ivory affair that was furtively exhibited to tourists at the Hôtel de Cluny. It consisted of a jointed iron belt, to encircle the hips, to which a rigid strip of iron was connected before and behind, somewhat after the manner of a T-bandage. This strip of iron was widened where it passed over the vulva, and at that place there was a slit-like fenestra with a serrated edge, the teeth being bent somewhat outward. At the situation of the anus there was another perforated expansion, circular in this instance, and that opening also was serrated. The whole was covered with ancient-looking velvet. The strip of iron which passed between the thighs was hinged to the pelvic girdle in front, but behind (perhaps to add to its discomfort) it was secured with a lock. The original lock was a remarkable antique, and bore the emblems of high nobility—perhaps royalty. On that account his friend had desired to keep possession of it, and therefore he (Dr. Thomas) had replaced it with a small modern padlock.

A Further Report upon Extra-uterine Pregnancy, embodying Six Cases.—Dr. THOMAS then read a paper with this title, the cases being supplementary to those that he had reported at the meeting held in 1882. They went to confirm the views which he had then expressed as to the innocuousness and the efficiency of the electric current as a means of destroying the vitality of the embryo in the early stages of extra-uterine gestation, with the result of converting the product of conception into a comparatively harmless mass. The paper gave minute details of the cases, for it was very important, the author thought, that with regard to an accident so uncertain of diagnosis the reader should be furnished with all possible facts to enable him to draw

his own conclusions as to the real nature of the cases. With all the difficulties that attended the early diagnosis of extra-uterine pregnancy, it was by no means impossible, Depaul to the contrary notwithstanding. He was convinced, moreover, that the accident was of far more frequent occurrence than was commonly supposed, and that in many instances the fœtus died early, and therefore the mothers recovered. This supposition was remarkably strengthened by experiments that had been performed by Leopold, who had found that fœtuses turned into the abdominal cavity in rabbits withered, and that the animals recovered. All this afforded theoretical support to the treatment of extra-uterine gestation, in its early stages, by destroying the life of the fœtus by means of electricity. Generally this was easy of accomplishment, and that, too, with currents not only not liable to injure the mother, but not even of very disagreeable intensity. In one instance, however, he had been obliged to use a galvanic current from forty cells. In advanced cases laparotomy still remained the only resource. In regard to this operation, it was generally best not to remove the placenta at the time, unless the fœtus had been dead for some time, so that the placenta had begun to undergo that decrease in its blood-supply which accompanied and followed the discontinuance of its functional activity. When rupture of the sac had taken place, the operation should be done at once, for the purpose of ligating the bleeding vessels, as was advocated several years ago by the late Dr. Stephen Rogers, of New York, and lately practiced by Mr. Lawson Tait, of England, and Dr. Charles K. Briddon, of New York.

Dr. MUNDÉ had seen four cases of extra-uterine pregnancy, but only one of them early enough for the employment of electricity. In that case, which had been published, the symptoms and the physical signs left no room for doubt as to the diagnosis, and it had been confirmed by Dr. Emmet without his having known the conclusion at which he (Dr. MUNDÉ) had arrived. The galvanic current was employed, and, although severe shock was manifested, the strength was carried up to that of twenty-four cells. This caused considerable pain, and was followed by collapse of such severity that rupture of the sac was suspected. Indeed, Dr. Briddon, to whom he had spoken of the case at the time, was so convinced that it had taken place that he urged him to perform laparotomy. This was not done, however, but morphine was used freely. The patient soon improved, and gradually recovered. Galvanism was not used further, but several applications of faradization were made. The mass gradually diminished in size until it was not more than one third as large as it had been, and the patient went abroad. He thought that in future he would try faradization first. Any other treatment than that by electricity, in the early stages, was a mere waste of time if nothing worse, although laparotomy before the occurrence of rupture, as had been done by Veit, was to be thought of.

Dr. T. B. HARVEY, of Indianapolis (present by invitation), asked if the uterus was enlarged in all cases of extra-uterine pregnancy, as was laid down in the text-books. He had seen a case in which, at the fourteenth month after conception, the uterus was of its natural size.

Dr. THOMAS thought that the explanation of that fact probably was that the uterus had undergone involution.

Dr. PALMER asked Dr. Thomas how late in the progress of a case he would consider the use of electricity proper.

Dr. THOMAS replied that he would not generally place any dependence upon it after four months or, at the latest, five months and a half had been completed, especially if he was satisfied that the fœtus was in the abdominal cavity, but would let the case go on with the view of resorting to laparotomy subsequently.

Dr. WILSON referred to two cases that had come under his observation. In one of them electricity was used, and the other was his well-known case of simultaneous extra-uterine and intra-uterine twin gestation. The question had occurred to him, whether laparotomy should be performed at once on the completion of the normal period of gestation, or whether it was justifiable to suffer the child to die, as the result of delay for the purpose of inducing shrinking of the placenta.

Dr. THOMAS thought that, when the child was living at the completion of the ninth month of pregnancy, it should be removed by abdominal incision at once, but that, if it was dead, delay should be practiced in the interest of the mother.

Dr. HOWARD had seen a case bearing upon the point brought up by Dr. HARVEY. The woman thought that she had been pregnant for sixteen months, and the uterus still measured four inches in depth. At the post-mortem examination the fetus was found decomposed. The case went to show that involution did not always take place at once after the death of the fetus.

Dr. BAKER had seen four cases. He had been struck with the difficulty of the diagnosis in the early stages, even with the aid of anesthetics. In one case, in which the rational symptoms were indicative of rupture of the sac, careful examination with the patient anesthetized did not corroborate the suspicion, and the patient died. At the post-mortem examination it was found that rupture had taken place.

Dr. REAMY coincided with the views that had been expressed in the paper, especially with regard to the limitations of laparotomy.

A Case of Tubal Pregnancy with Rupture of the Sac.—

Dr. Reamy having been called to the chair, Dr. MAURY read a paper with this title. The case occurred in a patient who had undergone the usual operation for laceration of the perineum. The uterus was distinctly enlarged, as felt through the abdominal wall, and there was a mass on the right side, in Douglas's *cul-de-sac*. The patient was suddenly seized with intense abdominal pain and shock—symptoms which were interpreted as indicative of the sac having ruptured and given rise to the formation of a hematocoele. Under treatment directed to the relief of the symptoms, reaction took place, and peritonitis followed, but the patient recovered. Six months afterward, only a small mass was to be felt in the situation that had been occupied by the sac. With all the advances that had been made in abdominal surgery, the author doubted if it would ever be practicable to make primary interference generally satisfactory in such cases, and he therefore advised waiting until the subsidence of the shock occasioned by the rupture.

The Limits of Vaginal Hysterectomy for Cancer.—

Byford being in the chair, Dr. MUNDÉ read a paper with this title. [It will be remembered that, at last year's meeting, held in Philadelphia, Dr. JACKSON read a paper in which he took the decided position that hysterectomy for cancer was an unjustifiable procedure. Dr. MUNDÉ's paper seemed to have been called forth by Dr. JACKSON's, and to have been intended as in some sort a reply to it, for the author said that the way in which Dr. JACKSON's paper had been received had given the impression in some quarters that the society had authoritatively expressed its disapproval of the operation.] Leaving Freund's operation out of account, for that had practically been abandoned, even by its promoter, except in certain very favorable cases, the question turned mainly on the frequency with which the disease returned after extirpation of the uterus by the vagina in cases where the operation could fairly be held to be justifiable, since it had been shown not to be so dangerous in its immediate results as to put it beyond the bounds of legitimate surgery. The statistics of eighty-two operations, by various surgeons, showed the follow-

ing facts bearing upon the question: Schröder had done the operation in thirty-four cases, in twenty-three of which a recurrence of the disease had taken place in from six to eighteen months, while in eleven there had been no recurrence at the end of two years; A. Martin had operated in sixteen cases, with eight recurrences (time not specified); Olshausen, in the same number of cases, had met with nine recurrences in from four months to two years and a half; Demons had had seven cases, with two recurrences in from five to nine months; Czerny had had five cases, and recurrence seemed to have taken place in two of them, after the lapse of from one to two years; Kufferth had had one case, and recurrence took place in five months; the author of the paper had reported one case, in which recurrence had taken place at the end of nine months; Burke had reported one, in which the patient remained free at the end of two years; and in a case reported by Boeckel recurrence was observed in two months. Of the whole number, therefore, there had been a recurrence within two years in forty-eight, while in thirty-two there had been none. This, to be sure, was not a very flattering showing, but it was enough, the author maintained, to entitle the operation to further trials, and it should not be condemned outright.

Dr. REAMY and Dr. JACKSON asked upon what duration of life after the operation it had depended whether the cases were excluded from the table, on the ground that death had been the direct result of the procedure.

Dr. MUNDÉ answered that all those in which death had taken place within a month of the operation had been excluded, although it was reasonable to suppose, as with regard to almost any operation, that some of those deaths had been due to intercurrent affections or some accidental circumstances which were not fairly chargeable to the operation itself.

Dr. JACKSON wished to emphasize his belief that any surgical operation should either alleviate suffering or prolong life; otherwise it was unjustifiable, and could not be justified by particular "runs" of successful cases. The operation in question accomplished neither of these purposes, unless we counted death as a relief from suffering. When the disease returned, the relapse was attended with the same suffering that had accompanied the original outbreak. In his paper, which had been so pointedly referred to, he had shown by calculations based on statistics that life was actually shortened by operations for cancer of the neck of the uterus. Dr. MUNDÉ's figures showed a slight reduction of the mortality since that time, but it was still to be shown whether or not lives had been prolonged. Did not all who were present, including the essayist, know that, on the average, patients did not live eighteen months after the operation? He (Dr. JACKSON) knew, indeed, of one solitary instance in Chicago in which vaginal hysterectomy had been followed by survival for two years and a half now, but such an occurrence was more than exceptional—it was phenomenal. The difficulty was, to determine how far the disease actually extended into the tissues: the microscopist could tell us the condition of what was removed, but he could give us no information as to how far the neoplasm had invaded what was left of the patient. The extension of the disease was not always continuous through the tissues, but detached foci might be formed. Certainly, the operation, even if it was to be tolerated at all, had a very limited field, and did not deserve to be generally substituted for other procedures of a less dangerous nature. As he had said last year, it was gambling with human life—staking what did not belong to us. What was meant by "successful operations"? It was not the removal of the organ that was our object, but the removal of the disease; when the latter manifested itself afresh it was not a recurrence, but a continuation—the disease had not been removed at all.

Dr. VAN DE WARKER thought the society should be very cautious in dealing with the questions raised in connection with the subject, lest the impression should again go forth that a more or less authoritative judgment had been given, one way or the other. Really, it was not so much a question of how many survived the operation, but rather as to whether there was any better way of treating the disease. In his opinion, there were other methods that were equally potent and far safer. He would divide cases of cancer of the uterus into two classes: those that occurred before the menopause, and those that occurred after that event. In the first class there was a vigor about the disease that almost insured its return, so far as he could reason from his own experience. It was seldom that the disease could be thoroughly removed in any way, but there were other measures than hysterectomy by which we might come quite as near success, and with far less immediate peril. Nevertheless, he would not contribute to any prejudice against the operation—it should be freely and fairly tested in proper cases.

Dr. ENGELMANN agreed with the author of the paper in almost every particular, interpreting him, not as urging the operation, but as pleading for its subjection to further tests. It might be said to stand upon much the same footing as oöphorectomy, concerning which we were not yet in accord. At present the operation was too young to have made its status, but it was gaining ground, and he knew of better results from it than had been given in the paper. We should do well to bear in mind the early history of ovariectomy, an operation that was now firmly established. As regarded hysterectomy, it was manifest that only those patients who had been subjected to it when it was very young, at a time when the technics might be said to have been comparatively rude, who had had time to live two or three years. Any conclusion drawn from those cases would be premature and unfair; we should wait for further results, for the after-histories of patients operated upon by the improved methods that had now come into use. The results were constantly improving. When patients survived the immediate effects of the operation, they were relieved of their sufferings, whatever the final outcome might be, and who could say that they had not a fair prospect of life?

Dr. PALMER thought the paper showed that the immediate risk from the operation was smaller than had commonly been supposed, and no doubt the mortality would be still further reduced—perhaps to ten per cent. A dangerous operation was not necessarily unjustifiable. The great obstacle to the one under consideration was the difficulty of ascertaining the exact extent of the neoplasm in individual cases. Of course, no one would think of performing it where the parametrium was invaded, but this question could not be determined in half the cases. In the case of the breast, we no longer depended on the state of the axillary glands, as made out by examination, accessible as they were, but always removed them in operations for cancer of that organ; but the remote parts that were liable to be infected from a cancer of the uterus could not be removed, and that fact constituted the great impediment to the success of hysterectomy. On that account, he thought the scope of the operation was likely to be limited to cases of sarcoma originating in the mucous membrane of the body of the uterus.

Dr. BAKER asked if Dr. Mundé meant to exclude the operation when the disease was limited to the cervix.

Dr. MUNDÉ replied that he would so exclude it, provided the case admitted of the removal of all the diseased tissue by any other method.

Dr. BAKER would agree, then, with the views held by Dr. Mundé. Some surprise having been expressed at the great number of operations that he had referred to last year, in the

discussion of the subject, he wished to explain now that he had had in mind operations of all sorts for cancer of the cervix, and not merely hysterectomies. He had had patients who lived longer after the performance of his own operation than any of those who had been referred to to-day, but one of those alluded to at the last meeting had died since, in consequence of a return of the disease. He thought that hysterectomy should be preferred to other operations in cases where the disease extended beyond the cervix.

Dr. SCOTT reported that the results of the operation had not been very favorable in San Francisco, where the mortality had certainly been as high as twenty-five or thirty per cent., but he had in mind one case in which an excellent and rapid recovery had followed its performance by Dr. Cushing, the case being one of epithelioma. The statistics of this operation were no doubt vitiated to a great extent by the necessity of assuming that the diagnoses were all faultless. Conservatism was not always to be adhered to strictly; neither, on the other hand, should we rush in where angels feared to tread. A brother practitioner in San Francisco had been successful with hysterectomy, but nevertheless had given it up, and had adopted a procedure very much like the one which Dr. Baker had described, and, for his own part, he would generally prefer the latter.

Dr. REAMY thought that it was unwarrantable to compare this operation with ovariectomy, as had been done by Dr. Engelmann, for in ovariectomy there was only one danger—that which immediately followed the operation; if the patient recovered, she was for ever safe from a recurrence of the disease. He had seen a number of cases of uterine cancer in which life had been remarkably prolonged without any operative interference, and such cases ought to be taken into account, for it might be that the assumed saving of life as the result of operations was illusory. Operations had improved, but the prognosis of cancer had not kept pace with that improvement. Cancer of the cervix might not return after thorough removal, but, when the disease had spread to the vaginal junction, it would return. It had not yet been proved that the operation prolonged life, but that was no reason for opposing its further trial.

Dr. CHRISTIAN FENGER, of Chicago (present by invitation), had misunderstood the voice of the society last year. There must be a field for vaginal hysterectomy in cases where supravaginal amputation could not reach the disease, and doubtless its practice would be continued until cases had been so accumulated that we should be in a position to generalize with regard to its merits far more satisfactorily than at present.

Dr. MUNDÉ was glad to find himself practically in accord with nearly all the speakers. If there was any room for fallacy in his statistics, the same was true of those that Dr. Jackson had brought forward last year. He admitted the justice of what Dr. Reamy had said about the impropriety of comparing hysterectomy with ovariectomy; but the time might come when the two operations could fairly be compared. It was true that there were two kinds of "successful" operations—those that cured, and those that simply failed to produce death, and it was only in the latter class, perhaps, that hysterectomy could be placed at present. It was a fact, too, that cancer patients did sometimes survive for a surprising length of time without any operative interference, but should we therefore stay our hands and never interfere? He repeated that he did not wish to be understood as the special advocate of the operation; but he would urge that it ought not to be discarded on purely theoretical grounds.

Thursday's Proceedings.

The Present Aspect of the Puerperal Diseases (the President's Address).—According to the programme, the PRESIDENT was to have read his address on the morning of the second day,

but at that time he was prevented from doing so by sickness. He now called Dr. Byford to the chair, and proceeded to read portions of the address which he had prepared. After some preliminary remarks on the purity of feeling which should characterize the conduct of those who were called upon to deal with such delicate matters as the surgical diseases peculiar to women, the proper subject of the address was reached—the different theories of the pathology and ætiology of the affections grouped under the term puerperal fever. In particular, the President reviewed the discussion that took place at the New York Academy of Medicine last winter. He incidentally expressed his surprise that it should be said of certain morbid organisms that they produced disease, and yet that they were powerless for harm when introduced into a healthy system. He could not reconcile the two statements. At the conclusion of the address he explained his method of treating the uterus after delivery, and showed some glass tubes which he used in administering intra-uterine injections. It was a matter of routine with him to wash out the uterus with a hot bichloride-of-mercury solution.

On motion of Dr. REAMY, a vote of thanks was passed for the address, and for the manner in which the President had presided during that portion of the time that his condition had allowed of his occupying the chair.

Some Remarks on the Occipito-posterior Position in Vertex Labors; with an Analysis of Thirty-five Cases.—Dr. SAWYER then read a paper with this title. The special point brought forward in the paper was, that in such cases anterior rotation of the occiput did not take place so frequently as was set down in the books; indeed, the author was not sure that he had ever witnessed it. Most of the cases that he had met with had been in primiparae, and he was inclined to think that the tense condition of the anterior abdominal wall in primiparous women was the cause of the position, by interfering with the anterior obliquity of the uterus that was found in pluriparous women. The child's body being so firmly forced back against the mother's spine, he thought it was better accommodated with the back directed posteriorly. For the rectification of the position, it was of the greatest assistance to place the patient on the side, in the English obstetric position, and he had found the manœuvre much facilitated by the use of a forceps of his own devising, a specimen of which was shown. It was so fashioned that the Shank and the blades formed one continuous curve. The paper was illustrated with a drawing copied from Snellie.

Dr. WILLIAM L. RICHARDSON, of Boston, thought that such cases were the most common cause of trouble to ordinary practitioners. He was obliged to disagree with Dr. Sawyer on some points, particularly with reference to rotation. He had always seen it occur at the pelvic floor, unless there was some obstruction in the excavation. The position could usually be detected early by abdominal palpation, the back being found situated to the right, while the anterior fontanelle was easily made out on vaginal examination. In cases that had been mismanaged, he should first remedy the extension of the head, and this he had often succeeded in doing by the use of the forceps applied in the reverse direction—i. e., with the concave border of the blades directed backward. Of course, the instrument should be removed when flexion had been accomplished.

Dr. REAMY thought that, although occipito-posterior positions were not rare, they were by no means so frequent as might be inferred from the number of cases with which Dr. Sawyer had met. Rotation would generally occur, sooner or later, but it was another question whether we should interfere to shorten labor. If we did interfere, it should be not because there was any doubt that rotation would take place, but because there was some particular feature in the case which made

it incumbent upon us to do so. In regard to manual rectification of the position, he had never been able to accomplish it with one or two fingers, and he therefore would wait until the cervix was sufficiently dilated to admit of the introduction of the hand. In attempting artificial rotation, we should pay attention to the details of the original position, particularly being guided by the fact of the occiput having been directed to the right or to the left side. He had used the forceps reversed, as described by Dr. Richardson, but most commonly he applied it "normally." He could not see the need of the position on the side, and the ordinary forceps would serve the purpose, he thought, quite as well as the instrument that had been shown.

Dr. JOSEPH TABER JOHNSON, of Washington, concurred with what Dr. Reamy had said with regard to the rectification of the position.

Dr. HOWARD spoke of the advantages of Tarnier's forceps in such cases.

Dr. ENGELMANN could not see that the forceps shown by the author of the paper was specially calculated to prove of service in cases of occipito-posterior position of the head.

The PRESIDENT thought the common cause of difficulty in these cases was the failure of flexion of the head to take place early, so as to favor synclitism, and often, as had been said by Dr. Richardson, the only interference necessary was to produce this flexion with the forceps. It was his experience that rotation would occur spontaneously in the vast majority of cases—always unless there was something abnormal. It was true that this failure of flexion was most commonly met with in primiparae. He knew of no satisfactory theory of the causes of the position. Rectification, either with the hand or with the forceps, would generally succeed if resorted to before the head had become engaged, but, when it was attempted at a later period, it was apt to prove unsatisfactory, on account of the head resuming its previous position when the correcting force was removed. In any case of pelvic deformity he would certainly attempt artificial rotation when the head was above the brim, but, after it had engaged, he would draw it down with the forceps, making flexion at the same time. Rotation would take place in consequence of the advance of the head, and not from any manipulation by twisting with the forceps. The instrument should be removed when the head assumed a transverse position, and often it would not need to be applied again.

Dr. SAWYER preferred the English posture simply as a matter of convenience. Perhaps the rarity of spontaneous rotation in his experience had been due to the fact that he had almost always interfered early. He laid no particular stress on the forceps that he had shown.

Dr. REAMY added, as to the frequency of posterior positions, that he had met with them about five times in every hundred cases.

A Rare and Fatal Form of Sepsis without Symptoms.—

At the afternoon session Dr. ENGELMANN read a paper with this title, the President-elect, Dr. Howard, in the chair. The reader related the chief features of two cases of the sort to which he alluded. There were really no definite symptoms, at least none at all calculated to point to a diagnosis, and those that were present varied from the phenomena ordinarily found in cases of septicæmia. A peculiarity of the cases, so far as he had observed, was that they all proved fatal. In puerperal cases the absence of symptoms was not quite so complete as in those that occurred independently of childbirth. The statement had been made by Dr. Barker that the symptoms of septic poisoning varied in intensity according to the amount of septic material that had been absorbed. From this statement the author would dissent, also from the same writer's view that the elevation of temperature was an index of the quantity of poison

that had been taken into the blood, for in these cases there was no fever. Besides the two cases reported, reference was made briefly to four or five others, and it was stated that they had occurred in connection with various morbid conditions.

Dr. RICHARDSON had seen five or six cases among puerperal women, and their nature had been ascertained post mortem. Without any special symptoms, the patients simply "faded out." In all his cases the pulse and temperature had been normal or nearly normal.

Dr. REAMY had seen a number of cases that answered to the description given.

Dr. JOHNSON had seen one case which he now thought was of the class under consideration. In that case the patient's friends had charged at the time that the death was due to the use of chloroform.

Dr. ENGELMANN closed the discussion with a review of the statements he had previously made, emphasizing the fact of the fatality of all the cases.

Papers read by Title.—During the meeting the following papers were read by title: The Hygiene of Pregnancy, by Dr. Samuel C. Busey, of Washington; Rapid Dilatation of the Cervical Canal, by Dr. William Goodell, of Philadelphia; The Physiognomy of the Vulva as a Sequence of Anal Disease, and the Cause or Sustaining Cause of Uterine Disease, by Dr. Isaac E. Taylor, of New York; The Early History of the Treatment of Vesico-vaginal Fistule in the United States, and the Statistics of the several Modes of Operating, by Dr. Nathan Bozeman, of New York; Periodical Symptoms in Uterine Disease, by Dr. George J. Engelmann, of St. Louis; Contributions to the Topographical and Sectional Anatomy of the Female Pelvis, by Dr. David Berry Hart, of Edinburgh, Scotland; Fibro-myomata and Fibro-cystic Myomata of the Uterus—their Diagnosis, Prognosis, Pathology, and Treatment, by Dr. R. Stansbury Sutton, of Pittsburgh; On the Ring of Bandl, by Dr. William T. Lusk, of New York.

The Business Meeting was held Wednesday evening. An amendment to the By-Laws was adopted by virtue of which nominations for fellowship need not in future have the indorsement of the Council, and an amendment to the Constitution making the limit of membership one hundred instead of sixty. Officers for the coming year were then elected as follows: President, Dr. WILLIAM T. HOWARD, of Baltimore; vice-presidents, Dr. WILLIAM L. RICHARDSON, of Boston, and Dr. PAUL F. MUNDÉ, of New York; secretary, Dr. FRANK P. FOSTER, of New York; treasurer, Dr. MATTHEW D. MANN, of Buffalo; other members of the Council, Dr. JOSEPH TABER JOHNSON, of Washington, Dr. A. REEVES JACKSON, of Chicago, Dr. HENRY P. C. WILSON, of Baltimore, and Dr. ELY VAN DE WALKER, of Syracuse. It was voted to hold the next meeting in Washington, on the third Tuesday of September, 1885, and the following Wednesday and Thursday. Dr. GEORGE GRANVILLE BANTOCK, of London, England, was elected an honorary fellow.

Members by Invitation.—At various times during the meeting the following-named gentlemen were invited by vote to take part in the proceedings: Dr. E. C. DUDLEY, Dr. W. E. CLARKE, Dr. T. P. SEELEY, Dr. N. S. DAVIS, Dr. LISTON H. MONTGOMERY, Dr. RALPH E. STARKWEATHER, Dr. A. H. BURR, and Dr. GEORGE H. RANDELL, all of Chicago; Dr. P. McCLOURE, of Dubuque, Iowa; Dr. HENRY G. DEARBORN, of Nashua, N. H.; Dr. J. H. CARSTENS, of Detroit; Dr. T. B. HARVEY, of Indianapolis; Dr. FRITZ NETZLER, of Stockholm, Sweden; Dr. FRANK WOODBURY, of Philadelphia; Dr. WESLEY M. CARPENTER, of New York; Dr. W. H. MYERS, of Fort Wayne, Ind.; Dr. J. H. RAUCH, of Springfield, Ill.; Dr. J. K. BARTLETT and Dr. WILLIAM FOX, of Milwaukee; and Dr. T. A. ROGER, of Montreal.

Miscellany.

The American Public Health Association will hold its twelfth annual meeting in St. Louis on Tuesday, Wednesday, Thursday, and Friday, October 14, 15, 16, and 17, 1884. The meeting will be held in Liederkrantz Hall, on the corner of Thirteenth Street and Chouteau Avenue. The following are among the papers that are expected to be read: The Hygiene of the Habitations of the Poor, by Major Samuel A. Robinson, of the District of Columbia, Dr. C. W. Chancellor, of Maryland, and Dr. W. K. Newton, of Paterson, N. J.; The Hygiene of Occupations, by Dr. G. H. Rohé, of Baltimore, Dr. Walter Wyman, of the Marine Hospital Service, and Dr. J. W. Chambers, of Baltimore; School Hygiene, by Dr. S. W. Abbott, of Massachusetts, Dr. E. M. Hartwell, of Baltimore, Dr. S. O. Richey, of Washington, and Dr. Felix Formento, of New Orleans; The Adulteration of Food, by the Hon. Erastus Brooks, of New York, Professor H. B. Cornwall, of Princeton, N. J., Professor C. E. Munroe, of the Naval Academy, Dr. V. C. Vaughan, of Ann Arbor, Mich., and Dr. J. C. Morris, of Philadelphia; Water Pollution, by Dr. Charles Smart, of the army, Dr. Henry B. Baker, of Michigan, and Dr. T. M. Stevens, of Indianapolis; The Disposal of Sewage by Irrigation or Chemical Action, by Dr. H. P. Walcott, of Massachusetts, Mr. G. N. Bell, of Newport, and Dr. W. J. Harris, of St. Louis; The Observable Effect upon the Public Health of Official Sanitary Supervision, by Colonel G. E. Waring, of Newport; The Work of Municipal and State Boards of Health, by their secretaries: Disease Germs, by Dr. G. M. Sternberg, of the army, Dr. L. Bremer, of St. Louis, Dr. W. W. Vinneedge, of Indiana, and Dr. W. H. Stillwell, of Tennessee; Cremation as a Sanitary Measure in Times of Great Epidemics, by Dr. John Morris, of Baltimore, and the Rev. J. D. Beugless, of the navy; A Survey of the Present Sanitary Situation in St. Louis (a series of short papers by city officials and local sanitarians); On Heating and Ventilation, by Dr. C. O. Curtman, of St. Louis; On Protective Spectacles, by Dr. A. Alt, of St. Louis; On the Prevention of Syphilis, by Dr. J. D. Gatch, of Lawrenceburg, Ind.; On the Hygiene of the Nervous System and the Mind, by Dr. C. H. Hughes, of St. Louis; and On the Sanitary Management of Railway Cars and Stations, by Dr. W. T. Parker, of the army.

The Health of Michigan.—We have received from the secretary of the State Board of Health of Michigan, Dr. Henry B. Baker, of Lansing, a report of the principal diseases prevailing in the State during the month of September, 1884. The report indicates that, as compared with the preceding month, there was an increase of typho-malarial and typhoid fevers, and a decrease of cholera morbus, cholera infantum, diarrhoea, and dysentery. Compared with the average for the month of September in the six years, 1879 to 1884, there was a diminished prevalence of intermittent fever, typho-malarial fever, diphtheria, pneumonia, and remittent fever. There was no marked increase in the prevalence of any disease reported in the month, compared with the average for that month. The temperature was higher, the absolute humidity was greater, and the relative humidity and the day and the night ozone were less. Diphtheria was reported from twenty-five places: Armada, Bloomfield, Detroit, Douglas, East Saginaw, Edmore, Fowlerville, Flint, Grand Rapids, Hastings, Handy, Ionia, Ishpeming, Ithaca, Kalamazoo, Marquette, Mendon, Muskegon, Port Huron, Prairie Ronde, Romeo, Sand Lake, South Haven, Vassar, and Wyandotte. Scarlet fever was reported from seventeen places: Cadillac, Detroit, Dorr, Dowagiac, Fairfield, Grand Rapids, Howard City, Ionia, Jerome, Kalamazoo, Monroe, Muir, Muskegon, Swartz Creek, St. John, Vicksburg, and Wexford. Measles was reported from Detroit and Whitehall.

The Health of the State of New York.—The "Monthly Bulletin of the New York State Board of Health" for August, in which it is stated that the returns from the country towns are still far from complete, shows that the total mortality reported for the entire State during the month was 6,950. The percentage of infant mortality was very nearly the same as for July, being 35.8. The percentage of deaths from diarrhoeal diseases was 24.8; in July it was 30.5. Twenty-two of the twenty-four cities in the State return an aggregate mortality of 5,611, corresponding to an annual death rate of 21.21 in a thousand.

Lectures and Addresses.

A CLINICAL LECTURE,*

DELIVERED (BY REQUEST) AT BELLEVUE HOSPITAL,
SEPTEMBER 20, 1884.By LAWSON TAIT, F.R.C.S.,
BIRMINGHAM, ENGLAND.

GENTLEMEN: The first case of which I have to speak this morning is a very typical one of a disease with which possibly many of you have heard my name associated. It is not a new disease, for we find in the writings of the authors of our medical classics that the disease is very well described. You will find, under the term "*colica scortorum*," a group of symptoms given which, to my mind, clearly indicate the disease of the Fallopian tubes of which I have to speak. The disease was also fully described and figured in text-books before I was born, and yet there are people in my own country who foolishly say that it does not exist, or that, if it does, examples of it are found only in Birmingham, where I live.

The patient in question is a young woman, about twenty-eight years of age, of very healthy appearance. She gives a history of a very definite kind, and she tells us that for five years her life has been one of prolonged misery. Her sufferings began immediately after marriage, with intense scalding pain in the vagina, accompanied by a profuse purulent discharge. She has never been free from pain since; and her menstruation has become too frequent and too profuse, always characterized by intense pain, this pain beginning some time before the period shows itself, and lasting throughout the time. Her appearance does not indicate serious disease, nor intense suffering; yet she has a very serious malady—a malady which is often fatal, and one which is accompanied by great agony; and it is entirely incurable except by the operation I am about to perform.

The disease I am speaking of is pyo-salpinx, and, before I operate, I had better tell you a little of the origin and course of the disease, and the difficulties and dangers incident to it.

This woman acquired gonorrhœa from her husband at the time of marriage. She does not know this, and there is no need that she should. The history is a complete and perfect one, for, if a woman tells you that soon after sexual intercourse she was attacked by pain and swelling in the passage, scalding in passing urine, and a profuse purulent discharge, you may assume that she has had a gonorrhœa inflicted upon her, and there will not be much probability of your being wrong.

Gonorrhœa has been considered until lately as a very harmless disease in women, but this is a great mistake. In men, gonorrhœa is a very serious disease. I do not see the disease in men at all, but I have heard from the lips of a master in surgery that in a man gonorrhœa is quite as serious as syphilis, and that a bad stricture is practically incurable, its effects being evident through

life. The urethra of a woman is so short and so distensible that stricture there does not occur; at least I have never seen it, nor have I heard of its occurrence, so that it must at least be very rare. But there are other organs in women affected by gonorrhœa in a very fatal way—in a way that gives rise to untold agony. Every one who deals in the special diseases of women knows the chronic endometritis which remains after a gonorrhœal vaginitis has been cured. But, until I pointed it out, some four or five years ago, the fact was not known, or at least had been completely lost sight of, that the gonorrhœal inflammation spread along the Fallopian tubes and gave rise to immense mischief. You know that, from time to time, the infundibular end of the tube becomes temporarily attached to the ovary, and, if there is a gonorrhœal inflammation going on, this temporary attachment becomes a permanent one, or it may be that the infundibulum becomes adherent to intestine, bladder, pelvic wall, or other object. In any way, the outer end of the inflamed tube gets occluded, and this is the first stage. This occurs with an attack of pelvic peritonitis, of which you can get a clearly defined history in very many cases, and, looking back on my experience in former years, I know now that at least one mysterious and unexplainable case of fatal peritonitis could have been explained as arising in this way.

You know, of course, that, like all mucous conduits, the Fallopian tubes have as one of their functions the secretion of a mucus. In addition to this, they take part in the special secretion of blood which forms the menstrual fluid. With one end occluded, and in a state of chronic inflammation, their secretions are exaggerated in quantity, as is the case always with mucous surfaces when inflamed, and we have the second factor of the disease produced—distension of the tube. When the uterine opening of the tube remains patent, the morbid secretion is squeezed out into the uterus, and there can be no doubt—in fact, I know it now for a certainty—that there are instances in which the tubes, distended even to a very large size between the menstrual periods, are emptied in this way by the contraction of their walls, this emptying being accompanied by agonizing pains like those of labor.

Let me pause here to say that not all the cases of pyo-salpinx can be traced to gonorrhœa, and that there are many other causes; also that, when the tubes are occluded and distended, the distending fluid may be serum or menstrual blood—not always pus. But the nature of the contained fluid is of no importance, so far as the symptoms are concerned; the sufferings are quite as severe in hydro-salpinx as in chronic pyo-salpinx. But the risk to life, in pyo-salpinx, from rupture of the tube and discharge of the pus into the peritonæum, is very great. So far as we know, this accident occurs in more than fifty per cent. of the cases. Such rupture, in hydro-salpinx, would probably be of little importance, and I know that its occurrence leaves the patient, for some time at least, free from suffering. But you can not tell exactly, before you operate, whether the patient will be found to suffer from hydro-, pyo-, or hæmato-salpinx. Therefore your diagnosis never will be

* The lecture was kindly written out by Mr. Tait for the journal.

exact. Even with my large experience, I am wrong about one case in five. I believe this patient has pyo-salpinx. We shall see.

In these operations I have had kind offers of assistance from critics without any kind of experience, who have told us, like a physician, of this city, that it is justifiable to operate in pyo-salpinx, but not in hydro-salpinx. I suppose he means that we should pull out the diseased organs, and, if we find hydro-salpinx, put them back again. No other meaning can be attached to his words. The rule I have long since adopted and acted upon is, if I find a woman suffering intensely from the symptoms I have described, with physical evidences of disease of the appendages, to advise her to submit to abdominal section, and to perform it if she accepts the responsibility. We are enabled to do this by the small mortality which now follows these operations since Listerism was abandoned.

Other proposals have been offered to deal with these cases by tapping them, but, as my friend Dr. Emmet happily expressed it to me last night, "You want a lot of finger-posts in there, and there are none." You can not tell where the tubes are; you can not even say, in many cases, that it is the tubes at all that are affected till you have them out. Such a recommendation can come only from a reading-room surgeon, not from one who talks from the operating-table.

You see that I have now removed the uterine appendages, and the operation was a very difficult one. I have made a very small incision—enough only to admit two fingers. As soon as I got inside the peritonæum I found the effects of the primary inflammation. Everything was massed together, and the omentum glued over the pelvis. Making an aperture in that membrane, I searched about till I found the fundus uteri, and in this I had a finger-post. Running from it, on the left, I found a dilated tube, and, gradually easing it from its attachments, I came on a large cystic mass. This also had to be separated with great care, and you saw that the hæmorrhage was pretty profuse. The adhesions were very firm, and great care is required in the undoing of such, for it is an easy matter to tear intestine, or even the bladder may be damaged. The great misfortune of these operations is, that no one, not even the operator, can see what is being done. The base of the tumor was secured by a ligature and removed, and the same procedure was carried out for the appendages on the right side.

You see that the tubes are occluded, and distended like small convoluted sausages, and, when I squeeze them, there exudes from the mammilla of the divided tubes a quantity of grumous pus. The disease is, therefore, pyo-salpinx, and the diagnosis was quite right.

Let me say only one word more about the skepticism concerning the real existence of this disease, and my method of treatment of it. This skepticism has been banished on this side of the Atlantic, because your surgeons have come over to me and have seen my cases, have watched them recover, and have taken the preparations with them for public exhibition. My friend, and your teacher, Professor Lusk, was skeptical, and he came over, saw a case, returned home, and speedily found a case, operated, and cured his

patient. New York is twelve days distant from Birmingham, of hard travel, and large numbers of your countrymen have come. London is only a three hours' easy journey from Birmingham, yet the London skeptics do not come to see me, and Sir Spencer Wells says he has never seen a case of this kind.

Two words I have to say in parting from you—the first, in answer to a question constantly put to me, as to why it is that I get such splendid results in England, while here your operations are followed by a terribly heavy mortality. I can see only one point to which I can draw attention, and that I ask you carefully to consider. There are too many of you engaged in the work. It would almost seem to me as if every one was anxious to signalize his life by some effort or two in abdominal surgery. This will never lead to success. It can only fall to the lot of a few to operate often enough for the obtainment of complete success. Your chief aim must be the exaltation of the art you practice, and the great majority need, therefore—ought, therefore—to practice self-denial, and hand over such cases to the few who can make their treatment the object of their lives.

For years I have felt a doubt as to the propriety of such operations being performed in a large hospital, and before such an enormous audience as this, and, until a few days ago, I have never so operated. Many of my beliefs have been rudely shaken, and the doubt I have mentioned may go the way of others. But, even if it should be justified by these patients' not recovering (and two out of the four are already out of danger), something has to be said on the score of the need for the justification of my practice by showing it to the multitude. If all four recover, then I may feel that my doubt has been undermined.

My last word is one of farewell. I can hardly speak without emotion of the overwhelming kindness I have met with in my short tour through your splendid country. You show here, to an extent I fear we have not yet reached in my own land, the tender grace of courtesy.

Original Communications.

THE USE OF COMPRESSED AND RAREFIED AIR, AS A SUBSTITUTE FOR CHANGE OF CLIMATE, IN THE TREATMENT OF PULMONARY DISEASES.*

By J. SOLIS-COHEN, M.D., Etc.,
PHILADELPHIA.

THE great desideratum in exiling *poitrinaires* is to secure to them an opportunity of being in the open air, so that their lungs shall have a proper respiratory diet. Such pabulum, taken naturally, is far superior to any artificial administration. But, for the benefit of individuals whose lack of money or whose domestic duties preclude their resort to a temperate climate, there is a substitute in periodic inhala-

* Read before the American Climatological Association, May 5, 1884.

tions of air subjected to modifications of pressure. In many cases fully as much good can be secured by this treatment as by change of climate, and in a few much more; though, in the vast majority of cases in which change of climate is advisable, it is but a poor substitute. Its efficacy, however, has never been appreciated in the United States, although fully recognized in Europe, especially on the continent.

For some twenty years I have made occasional resort to this method of treatment as suitable cases presented; but special lines of practice have so closely occupied time and thoughts that the method has never been pushed for the purpose of attracting patients, while little has been contributed by me to the literature of the subject, save that written in the two editions of my "Treatise on Inhalation" (Philadelphia, 1867 and 1876).

The time required for the proper administration of an inhalation of compressed or rarefied air—from twenty to thirty minutes—is too great for a busy practitioner to bestow daily, or twice a day, upon individual patients; and it is only by massing patients, and having them inhale simultaneously from a number of apparatus, that this department of practice can be rendered sufficiently remunerative to attract careful supervision. Hence it is mainly confined to institutions fitted up for the purpose, and has not become incorporated into private practice. Patients whose means permit them to purchase apparatus for their own use can be instructed how to take their inhalations at home; and the method of treatment will begin to receive the professional attention it merits whenever apparatus of moderate cost can be supplied for this purpose. Hitherto the apparatus constructed with this view have been too costly and too cumbersome. An approach to a suitable contrivance for inhaling compressed air has been made in my own office by the combined efforts of my brother, Dr. Solomon Solis-Cohen, and Mr. Charles Richardson, physicist in Queen & Co.'s establishment, Philadelphia.

This apparatus, like that of Waldenburg and some others, utilizes the gasometer principle—a principle which years of experimentation with different methods have convinced me is the best adapted to the purpose. By weighting the inner cylinder (air-chamber) at the bottom, accurately adjusting its diameter to that of the outer one (water-chamber), and pumping the air into it by means of a foot-bellows, the cumbersome arrangement of ropes and pulleys is done away with, and the size of the machine considerably reduced. One of these instruments (Fig. 1), which has been in office use more than six months, consists of an inner hollow cylinder 12 inches in diameter and 20 inches* high, open at the bottom, but having two shelves, as it were, upon which to rest the weights—as if the cylinder had been covered in, top and bottom, and a longitudinal strip cut out of the middle of the base. The outer cylinder, open at the top, is just enough larger than the inner cylinder to enable the latter to slide up and down in it without grooves or flanges upon either. A rim upon the inner cylinder prevents it from sinking quite to the bottom of the water-chamber—a

preservative device. A tank to catch the water displaced by pressure is placed around the outer cylinder, reaching about half way down, and communicating with the cylinder by means of a row of holes bored in the cylinder at the level of the base of the tank. The diameter of the upper rim of the tank is 16 inches. A line painted on the outer cylinder indicates the water level, and a line painted on the inner cylinder indicates how high it may be pumped without being thrown out of the water. Both of these points, while susceptible of calculation, are conveniently ascertained by experiment with the highest pressure intended to be used.

The weights are of lead, segments of circles in shape, so as to assist in maintaining the equilibrium of the inner cylinder. A very simple calculation will give the proper weight for every fraction of an atmosphere intended to be used.* Thus, with an air-chamber of 12 inches diameter, upon which there is an atmospheric pressure of about 1,696.50 pounds, we should need, in round numbers:

For $\frac{1}{10}$ of an atmosphere,	24 $\frac{1}{2}$ pounds.
For $\frac{1}{10}$ " " "	28 $\frac{1}{2}$ "
For $\frac{1}{10}$ " " "	34 "
For $\frac{1}{10}$ " " "	42 $\frac{1}{2}$ "

The inner cylinder weighs a little over four pounds. Placing on its shelves twenty pounds, we augment the pressure by $\frac{1}{10}$ of an atmosphere, and the additional weights are placed atop of it as required. A gauge may be attached at a slight additional expense; but it is unnecessary, as the pressure is verified by the manufacturer before delivery of the apparatus. Of course, the top of the inner cylinder is pierced with two holes, into which are fitted two goose-necks—one for the attachment of the tube from the bellows, the other for the attachment of the tube to the stop-cock and mouth-piece—Waldenburg's being at present employed in the absence of a better form. The water may be run in through either of these pipes, and drawn off by means of a stop-cock at the bottom of the outer cylinder. When it is desired to cleanse the apparatus, the inner cylinder may easily be lifted out. The expense of the gasometer, weights, bellows, and tubing is in the neighborhood of twenty dollars; but the manufacturers think that, if sufficient demand exists to warrant making the apparatus in quantity, this figure can be reduced to fifteen dollars. The accompanying diagrams will render the description of the apparatus clearer.

The immediate effect of inhaling compressed air is to dilate the lungs and thorax to a greater extent than can be accomplished by the deepest possible voluntary inspiration at the ordinary pressure. The inspiratory portion of the respiratory act is thus greatly facilitated. To avoid rupture of the air-cells, it is not safe, especially with invalids, to employ a greater pressure than from $\frac{1}{10}$ to $\frac{1}{6}$ additional atmospheric pressure at first, gradually increased to $\frac{1}{4}$ or $\frac{1}{3}$. The $\frac{1}{3}$ additional pressure need never be exceeded. This method of treatment is indicated in early phthisis, in chronic bronchitis, in the partial collapse of lung sometimes following pneumonias, and, in fact, in all cases in which it is desirable to augment the vital capacity of the lungs, except in those instances where there exists a strong disposition to

* A machine 18 inches high can be used; one 24 inches high will give better mechanical results.

* This has been ascertained by experiment to be the best size.

hemorrhage. As the increased pressure on the intrathoracic organs increases the general intravascular pressure, it

FIG. 2. Section showing the method of weighting the inner cylinder. At the level of the arrow, A, a row of holes is bored through the outer cylinder to permit the escape of water.

is easy to understand that such treatment is imprudent in individuals disposed to hæmoptysis, hæmatemesis, epistaxis, hæmorrhoids, or other blood-loss.

The immediate effect of *expiration into compressed air* is to impede that portion of the respiratory act. This will tend to dilate the air-cells and rectify collapsed lung by backward pressure, so to speak, thus accomplishing the same results as inspiration of compressed air. The only advantage gained is in the muscular effort necessary to breathe into compressed air, and this can be well utilized in cases in which it may be an object of importance to increase the power of the respiratory muscles by systematic gymnastic exercise. For weak patients the method is unsuitable. Tendency to hæmorrhage is a contra-indication for the process.

The immediate effect of *inspirations of rarefied air* is by diffusion to tend to diminish the pressure of the air in the lungs. The greater pressure of the atmosphere externally is demonstrated by recession of the intercostal parietes, and of the soft parts above and below the sternum. The method thus acts as a gymnastic exercise for the muscles of respiration. The special therapeutic effect approaches

that produced by residence at high latitudes, for which in certain cases it may prove an acceptable substitute.

The immediate effect of *expirations into rarefied air* is to exhaust a portion of the residual air in the lungs and thus favor the collapse of the distended air-cells. The indication for the practice of the method is found in asthma and in pulmonary emphysema. And here I believe the home treatment by apparatus is often more efficacious than change of climate.

Had the pressure of other duties permitted, these remarks would have been extended, and the value of the various plans of treatment would have been illustrated by the records of typical cases. Even in the study of pulmonary diseases alone, we need to consider the effects, both immediate and mediate, upon the heart and circulatory system in general, produced by the use of these methods. The systemic effects, too, such as increased appetite and improved digestive powers, in some cases of phthisis, deserve a modicum of attention. But the writer's object has been accomplished in simply recalling attention to a neglected therapeutic art, in the hope that some of those present, or some of those who may read the report of the papers presented at this meeting, may be incited to study the subject more thoroughly.

It may be added, in conclusion, that auscultation and percussion during respiration of air subjected to compression or rarefaction bring out in relief special phenomena obscure or doubtful under the ordinary methods of auscultation and percussion, while some sounds are evolved which otherwise escape detection altogether.

HERPES LARYNGIS.*

By S. H. CHAPMAN, A. M., M. D.,

NEW HAVEN, CONN.

HERPES LARYNGIS is a rare disease. During the past six years the writer has seen five cases, while of pharyngeal herpes his note-books give account of more than one hundred cases.

The proportion, then, is about one in twenty.

The disease is, probably, not so rare as it seems, since the difficulty of diagnosis is greatly increased by the rapid appearance and disappearance of the eruption.

No doubt many cases of so-called simple neuralgia are really cases of herpes, the eruption not being observed.

The cases will be first briefly described, and afterward conclusions be drawn from them, in so far as it seems possible from so small a number.

CASE I.—A lady, twenty-two years of age, soprano in one of the largest churches in Connecticut, consulted the writer in June, 1878, because of harsh, discordant voice, and entire loss of singing-tones. During the spring preceding she had suffered from one attack of malarial fever, and continuously from the general symptoms of dumb-ague. A week before her visit, pain began to be felt in her throat of a lancinating character, notwithstanding which she sang the day following with good tones; but, by Tuesday following, the voice became husky and suddenly discordant. There had been no cough, and no percep-

* Read before the American Laryngological Association, May 14, 1884.

tible expectoration. Her nervous system had been profoundly affected during these few days by pain, loss of sleep, agitation, and great anxiety. Her pulse and respiration were normal.

The physical examination showed a moderate congestion of the larynx and cords, and a deep, clean-cut, non-exuding ulcer near the middle of the left vocal cord, extending at least one third of the depth of the cord. Muscular action was perfect. In connection with this was also a pharyngeal herpes, and the same eruption upon the lips. The diagnosis was thus made easy, but the prognosis seemed to the writer doubtful.

The patient was ordered inhalation of tincture of benzoin with oil of eucalyptus, and the internal administration of quinine and arsenic, and was told that it was quite possible that the voice would remain permanently injured. In September she presented herself again, with the report that all pain had passed away after a few days from her first visit, and that, in two weeks' time, her voice had again become clear, but that she had not yet returned to her music. This the writer permitted her to do upon finding the larynx again in a normal condition.

CASE II.—A machinist, aged twenty-nine, living in a malarious district, having suffered more or less severely for several years from malarial disease in different forms, was taken ill about ten days before his visit (April, 1879) with intense pain in the throat, cough, some pain in swallowing, and slight dyspnoea. These symptoms were rapid in development, and accompanied by the nervous agitation and anxiety so prominent in Case I.

Physical examination disclosed large, irregular ulcers, with clean-cut edges, in both ventricles; the surrounding tissue swollen, but the vocal cords normal and muscular action perfect.

There appeared to be no eruption elsewhere upon the mucous membrane. The ulcers were so intensely painful, even from the air passing over them, that the attempt was made to reduce this by the local application of glycerin, of glycerin and borax, and, finally, of a weak solution of silver nitrate.

Instead of diminishing, it seemed to increase the irritation, and the same treatment was adopted for this as in Case I.

Anodynes were also found necessary. The ulcers healed slowly, but the pain and distress disappeared within a week.

In September, 1879, the patient presented himself suffering from a second attack, during which the eruption occurred on the right side only.

CASE III.—A gentleman, an editor by profession, aged twenty-seven, had, in the spring of 1880, a severe attack of malarial fever, following some days of shooting on Long Island.

The fever left him debilitated and suffering from the ordinary symptoms of chronic mild malaria.

In June, the day following an after-dinner speech, he was seized suddenly with severe pain in his throat, "agonizing," he said, in character, with fever and rapid pulse, accompanied by a feeling as of some "impending calamity." On the day after the pain was first felt he had difficulty in swallowing solid food on account of the pain produced during its passage over the epiglottis. Food seemed to stick in his throat.

On this account he became, within a few days, quite weak, took to his bed, and had the appearance of great illness. There was with it a constant tickling and stinging which caused a dry, wearing cough. He began to speak in a whisper, because a loud tone seemed to increase the pain. There was no great emaciation, but sufficient to make one think at once of tubercular laryngitis.

Physical examination showed a severe pharyngeal herpes, and a large, ragged ulcer with perpendicular walls, extending over almost the entire posterior surface of the epiglottis to the

left of the median line, and involving also a small section of the border of the epiglottis as well. The entire epiglottis seemed swollen and inflamed. Touching the ulcer with a silver probe produced exquisite pain and a severe attack of spasmodic coughing.

Upon questioning him, it was discovered that one of the peculiar affections following the malarial attack had been herpetic eruption, developed rather generally, but especially about the face and back.

The constitutional treatment by quinine, arsenic, and strychnine was adopted at once, and the local treatment consisted of inhalations of benzoin, oil of eucalyptus, and oil of hops. The pain from swallowing was so intense that the endeavor was made to coat the ulcer with benzoin in saturated tincture. This was quite successful, but it was necessary to renew it several times daily. The eruption was very slow in disappearing.

In three weeks the original ulcer healed, but there appeared at this time a second upon the opposite side of the median line, smaller in extent than the first; and since the border of the epiglottis was not implicated, the swallowing of food caused no pain. The entire duration of the disease was between six and seven weeks.

At that time he was ordered to the sea-shore, and fully recovered his health during the autumn.

His throat has been examined since then—the last time two months ago—and been found to be in perfect condition.

CASES IV, V, and VI are very similar to Case III—one of the patients a woman aged thirty-nine, and the others men of about forty years of age, living in good circumstances, but in specially malarious regions. The affection in all was situated on the posterior surface of the epiglottis. In all three, relapses occurred; and in one, Case VI, relapses have occurred so often that it is doubtful whether a permanent cure can be effected, except by change of climate.

In all three the nervous symptoms were very prominent. At first flesh was lost rapidly, and recovery came slowly.

In one, Case V, the writer expected the eruption before it appeared; on account of the preliminary symptoms, a careful examination of the larynx was made for several days, and was rewarded by the observation of the growth through all its stages, from a small red point to a vesicle, and finally to an open ulcer.

The following conclusions may be drawn from these cases, although it must be distinctly understood that any conclusions from so few cases must always be subject to modification:

1. There exists such a disease of the larynx as herpes.
2. Its character is that of a neurosis.
3. It is closely allied to herpes of the pharynx and other mucous membranes.
4. It differs from other forms only on account of the peculiar microscopic anatomy of the larynx.
5. It is peculiarly a disease of malarious districts, and one of the eccentric developments of malaria.
6. It simulates tubercular inflammation of the epiglottis. The differential diagnosis, however, is easy. It is based upon the extreme rapidity of development, the absence of fever, the history of malarial affections, the previous or simultaneous development of herpetic eruption elsewhere, and the rapid disappearance of the disease.
7. Its seat is usually the posterior surface of the epiglottis.
8. The nervous system is always profoundly affected.

THE THERAPEUTICAL EFFECTS OF THE INTERNAL ADMINISTRATION OF HOT WATER IN THE TREATMENT OF NERVOUS DISEASES.*

By AMBROSE L. RANNEY, A. M., M. D.,

PROFESSOR OF APPLIED ANATOMY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

A MUTUAL dependence may often exist between disordered states of the thoracic, abdominal, and pelvic viscera and some forms of functional disturbance of the nervous system. This is well recognized to-day by all neurologists.

The fact has been demonstrated, by a long array of clinical observations and physiological experiments, that the nerve-centers are not to be considered clinically as independent organs. The brain and spinal cord are to a certain extent but servants of the other viscera. On the other hand, the nerve-centers are occasionally the masters. They perform some of the functions (properly attributed to them in one sense) only in response to different forms of impressions conveyed to them from without. By means of vaso-motor and other varieties of nerve-filaments, sensory impressions made upon peripheral organs are now known to affect the general blood-pressure; to accelerate and arrest the action of the heart; to induce spasmodic and paralytic disturbances in special physiological centers of the brain and spinal cord; to create localized phenomena of defective nutrition and assimilation; and to excite reflex nervous symptoms in parts far removed from the seat of peripheral irritation. We also know that the growth of the viscera, as well as their physiological functions, hangs upon a reciprocal relationship between them and the brain and spinal cord.

I mention these facts as a preface to my remarks this evening, because they will be shown to have a direct bearing upon a theory which I shall advance respecting the action of heat (when introduced into the stomach) upon the various organs and tissues.

The tendency of the age, particularly in neurology, seems to me to manifest itself in endeavors to discover new medicinal agents, often to the neglect of simple remedies whose influence upon the system has not yet been thoroughly tested. Among the latter, to my mind, hot water stands pre-eminently at the head.

It may seem a startling assertion, but it is nevertheless a fact, that more persons among the laity are to-day taking hot water for various ailments than any single drug in our pharmacopœia. In many instances they may be doing so injudiciously and without proper grounds; but that they are employing this agent, for actual or imaginary ills of the flesh, by thousands can not be denied by any one acquainted with the facts.

The spread of the belief in the therapeutical value of hot water has traveled chiefly by word of mouth, as I know of only two articles in medical literature that have materially helped to popularize it. To employ hot water therapeutically could not have become so universal a custom unless great benefit had been bestowed by it upon many. My own

experience with it in the treatment of nervous diseases has led me to call the attention of the profession again to its use as a therapeutical agent, and to point out some of the results that may be expected from it, and also how it should be administered.

In no work upon therapeutics or neurology have I been able to find any record of experiments made to determine either the physiological or therapeutical effects of hot-water drinking. In most of them no reference even is made to it as a remedy.

It was first employed in 1858, according to Dr. Cutter, by Dr. J. H. Salisbury, who made use of it in a series of experiments undertaken upon animals and men, with reference to the effects of food upon the animal economy as a cause and cure of disease. These experiments were commented upon by the London "Lancet" as a "valuable American contribution to medicine," according to Dr. Cutter, who gives no reference to the number of that journal.

In 1883 (June 18th) Dr. Ephraim Cutter published in "Gaillard's Medical Journal" a short article giving a summary of Dr. Salisbury's conclusions. The same article again appeared in the "Lancet" of September 15, 1883 (without any reference to its previous publication), although classed as an "original contribution" to that journal. Dr. Salisbury can perhaps lay just claim to originality. He tested this agent upon himself, selected subjects, and animals, and his experiments were presumably conducted upon an honest basis, and with scientific acumen.

I have never verified his experiments, because I have been unable to get a reply, either from him or from Dr. Cutter, to my written requests for a reference to the journal in which they were published originally, or in which they were reviewed. I have tested the accuracy of many of his conclusions, however (according to Dr. Cutter's statement of them), in a clinical way. I deem it therefore but justice to Dr. Salisbury, with whom I am personally unacquainted, to express here my indebtedness to the views which he was the first to advance. Not only have I communicated personally with Dr. Salisbury and Dr. Cutter, but our courteous librarian kindly offered to make diligent search for all articles upon this subject. Thus far, he has been unable to find any, and all efforts by both of us to ascertain the date and channel of publication of Dr. Salisbury's original experiments have been fruitless.

Heat has been employed as a therapeutical measure in various ways for centuries. As a hæmostatic, hot water has lately become indispensable to the surgeon, although the red-hot iron was employed by Galen, and is still used to check hæmorrhage from bleeding mucous surfaces. As an antiphlogistic, heat is a household remedy. Who of us has not employed it in fever, inflammatory conditions, and many of the nervous disturbances of childhood that accompany these conditions?

Different temperatures are known to have widely different therapeutical effects:

1. Moderate heat, when applied to living tissues, causes a determination of blood to the part, with dilatation of its blood-vessels and an increased rapidity of the blood current. As examples of this action, I might cite the effects of the

* A paper read before the New York Academy of Medicine, October 16, 1884.

poultice upon suppuration, of the hot hip-bath and vaginal douches upon the catamenial discharges, of the hot bath upon the skin, and many others.

2. A higher degree of temperature, on the other hand, tends to cause contraction of the blood-vessels and to diminish the amount of blood in the tissues; hence the action of very hot water as a hæmostatic.

3. Intense heat, as illustrated in the application of the actual cautery to the skin (so lightly even as to cause neither vesication nor pain), produces a very marked contraction in the blood-vessels of organs and tissues that lie adjacent to the part cauterized. It is believed to-day that this effect is produced through the agency of the vaso-motor system of nerves, and that the contraction of the blood-vessels is a direct result of the shock produced upon peripheral nerve-filaments by the intense heat employed.

We have clinical knowledge that the actual cautery will produce a return of the normal habit of sleep, after chronic cerebral hyperæmia has produced wakefulness for years, if employed at the upper part of the neck. It will relieve the symptoms of spinal congestion, as no other known remedy will. It will often produce secretion by the kidney if applied to the loins, when congestion of that organ has led to complete suppression of urine. It will arrest neuralgic pains immediately in many cases. Finally, it will apparently exert an alterative change in tissues when persistently applied. In many forms of nervous diseases, this method of employing heat is recognized as an important aid in treatment. The cautery apparatus is to-day one of the most valuable additions to the neurologist's outfit. It is almost indispensable in the treatment of nervous diseases.

The benefits that result from the internal use of hot water, to which I shall call attention, must be due, in part at least if not wholly, to heat. Some of its effects are manifested, almost immediately, in organs not connected directly with the digestive apparatus. I will suggest further on in this article a theoretical explanation of these effects, based upon anatomical data relating to the nervous system.

RULES FOR ADMINISTRATION.

Let me state first, however, the method which should be rigorously followed in taking hot water for its remedial effects.

1. The water may be taken in doses of from one goblet to one and a half. An ordinary goblet contains about ten ounces. The dose must be modified in accordance with its effects.

2. *It must be drunk hot, and not warm (110° to 150°).* If necessary, fifteen minutes or more may be consumed in sipping a gobletful. Wooden cups prevent the water from cooling quickly. The water may be flavored with lemon, sugar, salt, ginger, etc., if necessary,* but it becomes very agreeable to the palate without such after the patient has taken it for a short time.

3. The dose must be taken *one hour and a half before*

each meal with absolute punctuality, and one at bed-time. My patients have the first dose brought to their bed-side and consume it before rising. The passage of the fluid into the intestine, or its absorption before the meal, is insured by this rule. The quantity taken daily must be modified according to the effects produced.

4. *The temperature of the water should be increased as fast as the patients can bear it.* It is remarkable how high a degree of heat some patients can endure after taking hot water for months. At first, such a temperature would blister the mouth. Below 110°, the heat is not sufficient, as a rule, to have any therapeutical effects, save as an emetic.

5. The administration of hot water *must be continued for at least six months*, in order to get its full effects. It will be some weeks, as a rule, before any beneficial effects become markedly apparent. It is not sufficient for a test of its value that it be given at irregular intervals, with variable degrees of temperature, and with no regard for the specific gravity of the urine and the proportion of solid ingredients secreted by the kidney.

6. The dose should be determined largely by the specific gravity and general character of the urine. If it falls as low as 1·010, the dose should be reduced, if necessary, to one half a pint. If it reaches 1·030, the dose should be gradually increased to a pint, provided that the daily quantity of urine has not been decreased to a point below the normal standard by profuse sweating. The average urinary secretion of a healthy adult should vary between thirty-five and fifty ounces for twenty-four hours. It may occasionally reach two quarts. The object of the treatment should be to bring the specific gravity of the urine to the standard of health, 1·010–1·022, and to keep it there.

7. *The use of cold fluids*, in the form of beverages, must be absolutely prohibited. Many patients have told me, after following this treatment, that they will never from preference drink cold water again.

8. *A restricted diet* is often necessary to the full effects of the treatment, in some forms of nervous derangements. It is my custom with some patients to forbid all sweets, pastry, fresh bread in any form, and fats. In other instances I employ the meat diet exclusively, the fatty parts being removed before cooking. The sour wines are not usually forbidden, nor is tea or coffee, unless they are apparently injurious to the patient. The condition of the subject, in respect to flesh, is my guide, as a rule, to the character of the diet prescribed, provided that marked disturbances to digestion or diabetic symptoms are not to be combated. If the patient is ill-proportioned as regards adipose tissue, I aim to reduce the weight gradually to the normal standard. This is estimated on the basis of the height, sex, bony framework, etc. Cutting down the saccharine and starchy elements of food will effect this reduction in weight rapidly. If the subject is thin and poorly nourished, I adopt the opposite plan often with good results.

(To be concluded.)

* Cinnamon, clover tea blossoms, sage, aromatic spirits of ammonia, and sulphate of magnesium have also been suggested. I often introduce a teaspoonful of Carlsbad salts into the morning dose, to relieve constipation, when it is obstinate.

The Chair of Pathological Anatomy at Leipsic.—The "St. Petersburger medicinische Wochenschrift" learns that Dr. Robert Koch, of Berlin, has been called to the chair, made vacant by the death of Professor Cohnheim, but that he has declined the offer.

THE RELATION OF LARYNGEAL TO PULMONARY DISEASES.*

By F. H. BOSWORTH, M. D.,

PROFESSOR OF DISEASES OF THE THROAT IN THE BELLEVUE HOSPITAL
MEDICAL COLLEGE, NEW YORK.

THIS topic was one among the list of suggested subjects for papers to be read at our meeting, and, at the request of a member of the committee, I have prepared a brief *résumé* of the question from the point of view that there is very little practical connection between diseases of the larynx and diseases of the lungs. As to syphilis of the larynx, I believe it has never been maintained that there is any connection between it and pulmonary disease. A very large number of these cases come under my observation each year at my clinic, and I have never yet seen a single case in which any involvement of the deeper air-passages could be traced to the morbid condition in the larynx. Syphilitic disease of the lung I have never met with, but in the few cases reported there is not, so far as I recall, a single case in which the pulmonary affection was complicated by, or seemed to give rise to, any laryngeal outbreak of the disease.

The same also may be said of carcinoma, lupus, and scrofula. The whole question, then, narrows itself down to catarrhal laryngitis and tuberculosis of the larynx. Acute catarrhal laryngitis I regard as a symptom of chronic laryngitis; in other words, the course of the chronic affection is characterized by recurrent attacks of mild acute inflammation, which I think rarely if ever occur unless there is a previously existing chronic disease.

Chronic laryngitis has filled a very large page in the literature of throat affections. Thirty years ago Garcia published his successful attempt to examine the larynx by ocular inspection during life, and thus gave a name to, and inaugurated the new specialty of, laryngology, setting a fashion which we have followed to the present day of basing our diagnoses on the results of a laryngoscopic examination, and restricting our therapeutic measures to topical agents applied directly to the laryngeal mucous membrane.

What is chronic laryngitis? Previous to the introduction of the laryngoscope it was a very commonly made statement that chronic laryngitis was due to syphilis or tuberculosis. I have even seen this statement made quite recently. That this assertion is utterly without foundation I need scarcely state. Syphilis in the larynx gives rise to certain definite, distinctive, and unmistakable lesions, such as mucous patches, superficial ulceration, deep ulceration, etc.; but these lesions are in no sense of the word inflammatory in character. So, also, in regard to tubercular disease of the larynx. This is a specific morbid process, characterized by the development of certain changes in the laryngeal mucous membrane which lead to ulceration and destruction of tissue; but these changes, whatever else they may be, certainly do not constitute an inflammatory process.

Chronic laryngitis, then, is neither a syphilitic or a tubercular disease; it is a simple catarrhal inflammation of the mucous membrane lining the larynx. The larynx, as the apparatus by which the voice is produced, is an organ of

much importance in the economy. It is also of importance with regard to the function, which somewhat adventitiously belongs to it, by which the glottis is opened with each act of inspiration—the so-called respiratory function of the larynx. As constituting a portion of the respiratory tract which is liable to become the seat of a catarrhal inflammation, I think its importance has been much over-estimated, for it constitutes a comparatively small portion of the respiratory tract. The trachea is lined by a mucous membrane which, in superficial area, is from six to eight times greater than that of the larynx, and a catarrhal tracheitis I regard as of more serious import than a laryngitis, and as giving rise to symptoms of a more troublesome character, and yet tracheitis is rarely made a subject of clinical study. The symptoms of a catarrhal inflammation are hyperæmia, over-secretion, swelling, and, as the case may be, interference with function.

Hyperæmia in the larynx in itself does not give rise to any marked symptoms. Swelling or tumefaction is never present in a simple catarrhal laryngitis to an extent sufficient alone to cause other than some interference with phonation, or impairment of voice.

Over-secretion is one of the symptoms of laryngitis, and yet the laryngeal mucous membrane, even in a state of chronic inflammation, possesses but a limited capacity for over-secretion. In the nasal cavities we find a mucous membrane which is endowed with a peculiar and very numerous set of glands which pour out a most abundant sero-mucous supply. This is demanded in order that in each act of respiration the air which reaches the lungs may be so far charged with moisture that it shall not rob the mucous membrane of the larynx and lower air-passages of its moisture, and thus produce irritation. The point which I wish to emphasize is, that the air which reaches the larynx and lower passages must be saturated or so far charged with moisture that it will not take up any moisture from these parts. This moisture must be, and is normally, supplied by the nasal membrane. When we remember that we take breath about twenty-five thousand times daily, we can form a proper estimate of the amount of secretion which normally must be poured out by the nasal mucous membrane. In the larynx, on the other hand, the amount of normal secretion is small. All that nature demands here is that the mucous glands and follicles shall pour out upon the surface of the membrane sufficient mucus to keep it in a soft, moist, and pliable condition, and this demand is easily supplied. In a chronic inflammation this normal secretion is, to an extent, increased, perhaps, but this is limited, because the capacity for secretion is limited.

Again, in regard to the impairment of function. Nature has endowed us with organs capable of doing far more work than they are ordinarily called upon to perform. This is true of most organs of the body, and is true of the larynx. The great function of the larynx is in phonation, and yet, as a rule, the ordinary function of phonation is not interfered with by a simple chronic laryngitis. Probably a majority of those present to-day have chronic laryngitis, more or less well marked, and yet few of us are conscious of any marked impairment of function therefrom.

* Read before the American Climatological Association, May 5, 1884.

The singing voice calls into use the highest capacity of the larynx, and, therefore, demands that the laryngeal mucous membrane shall be absolutely in a condition of health, and hence, in the singer, a chronic laryngitis becomes a matter of serious import, but serious only to the voice. A chronic catarrhal laryngitis, then, in itself as a disease, is a comparatively trivial matter. I mean by this that, if we confine our attention entirely to the laryngeal membrane, we find that the symptoms which may arise from the morbid process are of slight importance. Furthermore, I think some light is thrown on the subject if we glance at the literature of its treatment. Pretty much all of the mineral and vegetable astringents in the Pharmacopœia have been recommended for its cure, in solutions of all grades of strength; and sprays, brushes, sponges, probangs, and other devices have been used for carrying these agents to the affected parts. In a standard work published within four years, I have even seen recommended the application of a saturated solution of nitrate of silver. This latter suggestion would certainly seem to indicate that all other measures were inefficacious, for one would scarcely dare resort to this treatment unless as the very last resort. I once saw a patient—a physician—in whose larynx a one-hundred-and-twenty-grain solution of nitrate of silver had been used, and his condemnation of it was most emphatic.

At a recent meeting of laryngologists I listened to a discussion on the treatment of catarrhal laryngitis, the only practical interest in which was the candor and unanimity with which the conclusion was reached of the inefficacy of local applications to the larynx in this affection.

Chronic catarrhal laryngitis, then, I believe to be really a symptom rather than a disease. It is one of the results and accompaniments of catarrhal inflammation of the nasal mucous membrane, rather than a morbid process commencing in the laryngeal cavity. Many of the prominent symptoms which are often referred to the larynx are really to be directly traced to the nasal disorder. Just how this occurs I need not describe at length. The prominent cause of the laryngeal catarrh is in the interference with nasal respiration. Any of the causes which give rise to nasal stenosis will, sooner or later, cause laryngitis by the habitual mouth-breathing to which it gives rise; the dry, cold, and impure air reaching the larynx soon causes irritation and morbid changes in the membrane. The excessive secretion, also, from the nasal chambers, making its way into the fauces, passes down into the larynx, and acts as an additional source of irritation, and is, I think, often the source of the expectorated mucus which is supposed to be secreted by the larynx.

The extension of a catarrhal inflammation from the nasal passages to the larynx by direct continuity of tissue has been regarded as a frequent occurrence; but the more I see of these cases the more I am disposed to think that this does not occur. The mucous membrane of the lower pharynx, through which the inflammatory process is supposed to extend, is not a part of the air-passages properly, but is rather a part of the food-tract. It is covered with pavement epithelium, the air-passages being lined with cylindrical epithelium, and presents a hard, resisting surface, designed to admit with impunity the passage of hard and

often rude masses, which would be most irritating to the air-passages. Moreover, if the pharyngeal membrane is examined carefully, I think you will agree with me in saying that chronic pharyngitis, as involving the lower pharynx, is a comparatively rare disease.

As the result of a nasal stenosis, then, with mouth-breathing, and of over-secretion from the nasal passage, a chronic laryngitis develops as a symptom merely, and rarely, if ever, as a primary disease. In former years, when I treated this affection as a primary affection and made local applications to the laryngeal cavity, I gave temporary relief, and no more. And in this, I think, my experience was that of most others.

In the past three years I do not recall a single case of chronic laryngitis which has not been cured. During this period I have entirely abandoned all local applications to the larynx, and have treated the nasal disorder which I have found to be present in every case. In other words, I never succeeded in curing a case of chronic laryngitis until I commenced the practice of letting the larynx absolutely alone. I do not mean to say that I have made no topical application to the larynx in this time. I have done so not infrequently, but only as a matter of temporary relief, and, perhaps, at the solicitation of the patient. Several of these cases have been those of professional singers whose voices were breaking down as the result of laryngeal catarrh. The restoration of voice in each case was complete. This, I think, is to be regarded as a perfect test of the completeness of the cure.

In many cases, then, and I certainly believe they are a very large majority, if not all, chronic laryngitis is a symptom rather than a disease, regarding a symptom as a diseased condition which is caused by some morbid process which has set in primarily elsewhere and is only remedied by treating its source or cause; while a disease is a morbid condition which affects the part primarily, and is remedied by directing measures to that part. If this, then, is the correct view, the effect of a chronic laryngitis upon the lung-tissue is but slight. A morbid condition of the lungs may possibly give rise to a mild laryngeal catarrh, but the latter disease is of so trivial a character, and is so completely masked by the more serious pulmonary disorder, that it can scarcely be said to complicate it. The cause of the laryngitis is to be found in the constant and abnormal irritation which is kept up in the larynx by the cough which accompanies the lung disorder. That the constant bathing of the laryngeal membrane by the more or less offensive discharge from the lung is a source of laryngeal disease, as stated by Louis, is very questionable. The answer, then, to the question of the relation between catarrhal laryngitis and pulmonary disease, I think, may be given with some positiveness. The relation is but very slight.

There is but one other question to which reference has been made, and that is concerning tubercular disease of the larynx. About 30 per cent. of cases of phthisis pulmonalis have been found, on post-mortem examination, to have been tubercular disease of the larynx. On the other hand, no single case of laryngeal tuberculosis has ever yet been described in which, on examination, the lungs did not present evidence

of the same morbid process; and yet, it seems to me, there can be no question that the disease may occur primarily in the larynx and subsequently develop in the lung. This possibility has been questioned, many observers whose names carry much weight of authority insisting that the primary tuberculosis was in the lungs, and that, when the laryngeal disease developed, the lung disease was masked by it; or possibly that the tubercular process, while present in the lungs, was not recognizable by physical signs. It has always seemed to me that the question of the possibility of a primary laryngeal tuberculosis was an unnecessary one. There are few tissues or organs of the body in which tubercular disease may not occur, and, so far as I know, this possibility has never been questioned. When we come to the larynx, however, commended by Virchow to those "who wish to know true tubercle," the possibility of its primary development here is questioned. The mere fact of its presence at any time in the larynx is sufficient answer to the question. When it does develop in the larynx, it is as a new center of development, and not by extension by continuity of tissue. It would seem, then, to be utterly illogical to state that the larynx, of all the organs of the body, is exempt from a primary deposit of tubercle. What, then, is the influence of this primary laryngeal tuberculosis on the lungs? Sooner or later there will develop pulmonary phthisis. In all medical literature there is no case in which this has not occurred. That it stands in the direct relation of cause and effect can not be said, for undoubtedly, in every case, behind them both stands the constitutional condition which invites the disease; but that the laryngeal disease is a most active, exciting cause of the pulmonary phthisis can not be questioned.

As regards the influence of pulmonary phthisis in causing a laryngeal phthisis, not much can be added to what I have already said. Certainly by far the most active and most frequent appreciable cause of laryngeal phthisis is pulmonary phthisis. If there are any other active, direct causes of the disease, their connection is most difficult to trace. Do the constant cough, purulent discharge, etc., of the pulmonary disease act notably to produce the laryngeal disease? When we consider the large number of larynxes which are subjected to these deleterious influences, and the small percentage which develop tuberculosis, I think we are bound to conclude that their bad influence has been overestimated.

CASE OF BRAIN DISEASE (PROBABLY SYPHILITIC), WITH AUTOPSY.*

By LUCY M. HALL, M. D., BROOKLYN, N. Y.,

LATE PHYSICIAN TO THE STATE REFORMATORY PRISON FOR WOMEN, SOUTH FRAMINGHAM, MASS.

M. H., aged sixteen years, single, was committed to the Reformatory Prison for Women, June 2, 1883, for lewd and disorderly conduct. She was a slight, delicate, imperfectly developed, and very nervous girl. Her father was a confirmed inebriate; her mother was healthy, and of good habits.

About December 1st the patient lost appetite, and her pallor and nervousness increased. She did not complain, and contin-

ued in the discharge of light duties until January 24th, when, upon meeting her in one of the corridors, I noticed something so startling in her appearance (an unusual pallor, with great brilliancy of the eyes) that I immediately ordered her to the hospital. She was examined at 7.30 o'clock p. m.

The pulse was 120, wiry; temperature 102° F.; respiration 28 a minute; tongue lightly furred, and very pointed when protruded; bowels constipated; appetite poor. She complained of a dull pain in the left temple. The right pupil was somewhat larger than the left, both being moderately dilated. There was dullness on percussion, and bronchial respiration over the upper portion of the right lung. I was unable to elicit any history of syphilitic infection, or to discover any of the characteristic lesions of that disease. Menstruation had not occurred for five months.

During the early part of the examination she showed no embarrassment in answering the questions which were put to her, but soon I noticed that she appeared to hesitate, seeming unable to command the words which would express her ideas. Suddenly she became much bewildered, used words which conveyed no meaning, hesitated, finally became hopelessly involved, repeated "ah" or "why" a great many times, then sat silent, looking dazed and troubled. With each fresh question she would renew her efforts, with the results above noted. (Afterward I learned by careful inquiry that for several days she had been subject to less marked attacks of bewilderment and inability to express herself in words, but the matron in charge of her had sent her to rest and recover herself, not thinking that the condition was serious.)

January 25th.—At three o'clock a. m., the patient was awakened from sleep by a sudden and severe attack of vomiting. A large quantity of thin greenish fluid was evacuated. Subsequently the administration of a cathartic was followed by free movements of the bowels.

During the day she was weak and languid, but could reply to questions without embarrassment.

Evening.—Temperature 100° F., pulse 118, thin and hard; respiration 24.

26th.—At three o'clock a. m., vomiting occurred as upon the previous night. Severe localized pain in the left temple was now complained of. Temperature 102° F., pulse 110, extremities cold. Ung. belladonna. et hydrarg. was applied over the seat of pain, also an ice-cap. Heat applied to the extremities.

The history of the next few days showed no improvement. All efforts to control the terrible pain in the left temple were futile, or only temporary in their effects. The patient was very restless, moaned almost constantly, and suffered from extreme nausea, being able to retain but little food or medicine upon her stomach. The urine was scanty and high-colored, the specific gravity being 1.024, and the reaction acid. A slight deposit of urates was obtained, also sugar in small quantity.

Iodide of potassium was ordered in doses of from one to eight grammes, as borne; also, inunctions of oleate of mercury as the basis of the treatment.

February 4th.—Small excavated ulcers on the side of the tongue were found.

The pain in the left temple continued with varying intensity. Temperature 102° F., pulse 115. Projectile vomiting without nausea.

6th.—Temperature 101° F., pulse 90. Head symptoms no better. Pain at the left temple paroxysmal, causing the patient to cry out sharply. There was also pain over the entire frontal region and at the vertex. The teeth were covered with sordes; the tongue was protruded with difficulty, and was thickly covered with white fur. Food was retained by the stomach, the bowels were constipated, the abdomen was retracted. A good deal of

* Read before the Brooklyn Pathological Society, September 25, 1884.

pain in the bowels was complained of, but there was no tenderness upon pressure. The urine continued to be scanty and high-colored, containing traces of sugar. The patient complained of feeling chilly, and again hot at short intervals.

10th.—Temperature 103.5°, pulse 98. There was a dry, brown stripe in the center of the tongue. Nausea extreme.

11th.—Temperature 102.1°, pulse 100, somewhat irregular. A sticky, sanguineous secretion covered the lips and teeth, also the sides of the tongue. (The center of the tongue was still brown and dry.)

Evening.—The patient was dull and stupid, seemed to be sleeping, but when disturbed would insist that she had not slept. Anorexia was complete, and all substances were immediately rejected by the stomach. Food and medicine were administered by the rectum.

14th.—The patient had continued in a semi-comatose condition, but was conscious when aroused; slight rigidity of the muscles of the left side was noticed. Temperature 102.9°, pulse 130, weak. When the patient was placed in the dorsal position the respiration became very irregular, quick, and stertorous for four or five breaths, followed by an interval of from ten to twenty-five seconds, then a few short, shallow breaths, then stertorous again. When she was changed from this position the breathing became regular.

15th.—Temperature 103.8°, pulse 130; coma slowly deepening; face cyanotic. When aroused, she recognized those about her, but spoke indistinctly.

The pupils responded feebly to light; both were dilated, the right larger than the left.

16th.—Temperature 102°, pulse irregular, thready, 132. The skin was dry and the face pale. When loudly spoken to she would respond feebly but understandingly, then almost immediately relapse into unconsciousness.

Large, thin fecal stools passed involuntarily.

17th.—Temperature 102.9°, pulse 124–132, coma complete. The pupils were widely dilated, the iris presenting a mere line at its outer margin in the left and its inner margin in the right eye.

At twelve o'clock (noon) a decided convulsion, the first and only one, occurred, clonic in character but of short duration. Extreme cyanosis of the face followed this. Slight twitching of the muscles of the face and of the left hand occurred at intervals. The diarrhoea continued.

18th.—At 3 a. m. the breathing became markedly stertorous and irregular. Slight paralysis of the facial muscles of the left side was observed for the first time.

At 10 a. m. the tongue was swollen, the left half being half dry, the right half moist; mouth slightly drawn toward the right side; face cyanotic. The respiration was very irregular, varying from four to seventy-two a minute. Pulse 170.

At 11 p. m. the temperature rose to 106.2°. Death occurred at midnight.

In my absence the autopsy was made by my colleague, Dr. Eliza M. Mosher, assisted by Dr. L. M. Palmer, of South Framingham. Dr. Walter Channing, of Boston, was also present at the special examination of the brain.

Autopsy, nine hours after death: Rigor mortis well marked; body well nourished; skin of unusual bluish tint. Post-mortem congestion of most dependent parts. Abdomen, pelvis, and brain examined. Nothing of especial interest was found in two first cavities.

Brain.—The scalp contained an abnormal quantity of blood in its vessels. Skull of medium thickness. Dura mater strongly adherent to inner table of skull over left half anteriorly, somewhat thickened, and easily separable into two layers over both anterior cerebral lobes, but most marked on left side. Sinuses

filled to repletion with dark blood of syrupy consistence. Surface of dura mater along the line of the longitudinal sinus thickly studded with tallow-like bodies, from the size of a millet-seed to that of a grain of wheat, attached to the dura mater by a short pedicle.

Pia mater slightly opaque (milky in appearance), markedly so over the left lobe anteriorly and over the median portion of the convex surface of the cerebellum. Its contiguous surfaces were strongly adherent along the margin of the fissure of Sylvius (left), binding together the anterior and middle lobes. The vessels were greatly congested over the entire convexity of the hemispheres, the capillaries presenting everywhere an unusually beautiful arborescent appearance. The vessels of the left side, in the region of the third frontal convolution, were especially large, the middle cerebral vein of the left side being distended to nearly twice the size of its fellow. Tallow-like bodies, similar to those found along the longitudinal sinus, appeared in great numbers in this region as well as on the lines of the larger vessels of the convexity beneath the pia mater, and more or less imbedded in it. Upon the left side some of these growths had attained to the size of a large pea, and, upon section, were found to be much softer than the smaller ones, their contents being of the consistence of thick cream. Whether these were morbid growths, or Pacchionian bodies which had taken on morbid action, we were unable to decide.

The growths described were like the small figures in size and shape, always lying along the lines of the vessels.

Upon lifting the brain, a quantity of serum, apparently about six c. c., was observed free in the basal region. The structure of the posterior and middle lobes appeared healthy at the base, but gradually presented an unusually firm consistence as the vertex was approached. The entire anterior lobes were less firm than in the healthy brain.

The bases of the second and third convolutions upon the left side were so soft that the handle of the scalpel, laid lightly upon them, penetrated the brain substance.

Section of the left anterior cerebral lobe showed a partially absorbed hæmorrhagic infarction of the third, or Broca's, convolution, occupying about one half of its extent. (Shown in the diagram.)

The process of softening had extended forward through the second to the margin of the first convolution, and upward, encroaching upon the lower portions of the fourth and fifth convolutions.

On transverse section, marked congestion of the vessels was

everywhere noticeable. The ventricles contained a small quantity of serum.

Weight of the brain, 1,560 grammes.

That this was a case of early implication of the brain from syphilis is probable.

The cessation of the menses, so often occurring in nervous young women during the earlier stages of syphilis, the insidious and painless progress of the disease up to the time of her removal to the hospital, the *embarras de parole*, the retention of consciousness during the entire course of the illness—all point to syphilis as the cause, as do also the anatomical lesions, viz., the sores in the mouth found ante mortem, and the brain softening, the growths and other evidences of morbid processes, found post mortem.

The degeneration of the arteries from syphilitic new formations is forcibly described by Heubner ("Von Ziemssen's Cyclopædia," pp. 309–311, vol. xii). He also adds that "this degeneration most frequently affects the carotids and their branches, the arteries of the *fossa Sylvii*, and of the corpus callosum."

Upon page 308 he speaks of rare cases where the syphilitic growths make their appearance in the form of numerous miliary nodules upon the dura mater and in the soft membranes. "Engelstedt describes one such case, as well as Leon Gros and Lancereaux."

The almost entire absence of external lesions is not a rare condition in these cases. Engelstedt states that in twenty cases out of forty-one he found the syphilitic nervous disease the only symptom.

Brain affections at so early a stage of the disease as in this case is probable are somewhat rare. Heubner states that "these rapidly progressive cases are just the ones which generally occur at an unusually early period of the syphilitic disease, three of eleven cases of this character occurring during the first year after infection." Also that "hereditary predisposition to nervous diseases . . . undoubtedly plays an important part." Also, "It is highly probable that an organism whose nervous system is already by inheritance in a condition of unstable equilibrium may be affected by nerve syphilis, both easily and at perhaps an early period, when subjected to infection."

Book Notices.

Atlas of Female Pelvic Anatomy. By D. BERRY HART, M. D., F. R. C. P. E., Lecturer on Midwifery, School of Medicine, Edinburgh; Author of "Manual of Gynecology" (with Dr. Barbour), "Structural Anatomy," etc. New York: D. Appleton & Co., 1884. 4to, pp. 89–iv, 87 plates. [Price, \$15.]

The recognized value of Dr. Hart's lesser contributions to the topographical anatomy of the pelvis and its contents in women will doubtless lead his many readers in this country to a careful study of this, his most elaborate work in that department of gynecology. Since Savage's well-known work appeared, a number of additions have been made to our knowledge of the subject, in Germany, in Great Britain, and in this

country. Of all these Dr. Hart has availed himself to the utmost, not as a mere compiler, but in a spirit of legitimate criticism. He has tested his own observations by those of others, and *vice versa*, and the result is that speculation and crudity have been well nigh eliminated. That there was need of earnest work being done in this department, the glaring inaccuracy of many of the figures in most of the text-books, even at the present time, abundantly shows; and that the labor of detecting their fallacies has been arduous will be appreciated by any one who has ever attempted the task. Such a work as this, therefore, is of a nature to entitle its author to the gratitude of the profession.

There is still much that is doubtful in pelvic anatomy, particularly with regard to topography. In his treatment of those doubtful points Dr. Hart's moderation and freedom from the bias of preconceived theory are no less conspicuous than his intelligence. Indeed, throughout the book, nothing is set down as fact unless it seems to rest on a foundation too substantial for dispute. But the work is not a mere array of facts; it embodies a clear conception of what may be called the philosophy of the pelvic structures, so far as our present knowledge admits of such a conception, and, furthermore, it lays that conception before the reader tersely, intelligibly, and convincingly. It is not trivial niceties that the work deals with, but matters that are growing more and more to mold the gynecological practice of the day, and must continue to do so. Side by side with the statement of a fact we find its practical application, and the whole contents form such a natural sequence that a study of the work is well calculated to impart a real knowledge of the subject rather than a mere impression of a detached catalogue of facts.

Concerning the plates nothing but praise can be spoken; they are simply faultless in their mechanical execution. The typography is excellent, and the paper of the best. A short preface by Dr. Skene introduces the book to the American profession.

MEDICAL STUDY ABROAD FROM A MORAL STANDPOINT.

It is not our purpose to deliver a lecture upon ethics, but simply to make a few suggestions founded upon certain facts that are within our knowledge. It is undeniable that a strong impetus has been given to foreign medical study among our countrymen, both by the words and the writings of those who have enjoyed that advantage for themselves, and by the general and deeply felt need of a broader and more thorough training on the part of American practitioners. The details of the educational facilities to be had in Europe were ably set forth by the author of the article on the subject that appeared in our Students' Number, so that nothing further need be said as to the methods of study and the most favorable localities for special work. It may safely be assumed that the American medical graduate now goes abroad with a clear knowledge of the best ways and means of employing his time—a legacy bequeathed to him by his less fortunate predecessors.

There is one point, however, which has received little or no consideration, although it is so important that no excuse is needed for urging it upon the earnest consideration of the young physician. In times past a man could expect to make capital out of the simple fact that he had "studied abroad," but the glamour of the thing has worn off, and the laity as well as the profession now demand proof, not merely of time spent in study, but of time *well* spent. Real and not hypothetical results are the only ones accepted. Therefore, when a man returns with the supposed additional finish to his education, it is right that society should ask of him, and above all that he should ask himself, whether there has not been something lost as well as something gained.

The motives with which medical men go abroad are as various as the men themselves. A few have a clear idea of what they wish to do, and they do it. That they are in the minority, every thoughtful observer will acknowledge. It is noticeable that such men are generally heard from again. Others leave home with the laudable, although mistaken, ambition to cover the whole field of medicine in their study. The third class, and the largest one, comprises those who have no definite idea of just what they wish to undertake; in fact, they are somewhat in the position of the irreverent theological student who, having been asked what he intended to do, is reported to have answered, "Damfino." It is to the latter class especially that our present remarks are directed.

Each one of us can call to mind some man who was spoiled by going to college, who would have made a far more useful member of society had he remained on the farm or in the workshop, and not sought to improve upon the status handed down to him. We have no hesitation in asserting that many a medi-

cal student who would have made a steady and honorable member of his profession, had he entered upon its duties at once on leaving his college or hospital, has been spoiled by his residence abroad, where he has broadened his professional knowledge, but suffered an irreparable loss in moral tone, in delicacy of feeling, and in tenderness toward the suffering. This is no cant—it is simply an every-day experience. It is unnecessary to urge the trite remark that an educated physician is something more than a cyclopædia of facts or an infallible diagnostician—that he is, or should be, an honorable gentleman, and that, too, not for utilitarian reasons merely, but because it is *in him*. The thin varnish of Continental *politesse* or indifference is not suited to our society; it is decidedly out of place, and the young man who acquires it abroad must simply unlearn it on his return.

Assuming, then, that a liberal professional education is not enough in itself to secure success (to urge no higher motive), it may be asked with some pertinence whether other and more delicate qualities are likely to be cultivated abroad. We have no hesitation in answering this question in the negative. Indeed, the man who starts with the instincts of a gentleman must be on his guard lest he lose what delicacy he has. With those who have never been particularly troubled with delicate feelings, the result may readily be inferred. The "free and easy" moral atmosphere of the great Continental capitals, notably Vienna; the light regard in which woman is held; the perfect subjection in which patients are kept; and the cold-blooded way in which those patients are treated—all of these are dangerous elements in the question of foreign medical education. Add to them the entire irresponsibility of young men in Vienna, even to society, which exercises some restraint at home, and it will be acknowledged that he must be an individual of strong character and absolute devotion to a high ideal who returns home as clean a man as when he went. Again, methods of examining and treating patients are learned which it would be positive professional suicide for a man to practice at home. Whatever degree of tenderness and consideration he may have acquired is lost, and, when he begins private practice in his own country, he finds that he must go back and reacquire his former tact and suavity. This is the objection to German gynecology, for example, especially when the student has never studied that branch in any other school.

Enough has been said to lead the reader to admit the possibility that there are two sides to the popular question of foreign study. Far be it from us to cast any reflection upon the value of the intellectual training which may be acquired. Our only object is to show, and that without any intention of writing *ex cathedra*, that many men would serve their day and generation better by not going abroad to study, and that those who do go need to exercise some caution lest they return home not broad and earnest physicians, but soulless "scientists."

THE FIFTH VOLUME OF THE INDEX-CATALOGUE.

It is most gratifying to be called upon so soon to chronicle the appearance of a new volume of this gigantic work. If its

indefatigable director had nothing else on his hands, the rapidity with which it is pushed forward could not fail to excite the admiration of all those who have the slightest conception of the difficulty of the task. But Dr. Billings's activity, as everybody is well aware who keeps the run of what is going on in the profession, is constantly displayed in many undertakings that have nothing to do with the preparation of these volumes. Taking this fact into consideration, and especially the enormous labors upon which he must by this time have entered in connection with the organization of the next International Medical Congress, the steady progress made in the work of completing the Index-Catalogue—and that, too, without any deterioration in its quality, so far as we have been able to observe—can only be regarded as marvelous. Whatever may be the amount of assistance, advisory or clerical, at Dr. Billings's command, at least the direction of the work must fall upon him continually, and even a labor of love may become a severe tax upon one's endurance. Yet, we think it would not be over-estimating the appreciation with which the profession look upon the work to declare it ample to sustain and encourage a man even under such a mountain of toil. It is doubtless to this circumstance in no small measure that we owe it that the author of the catalogue has not lost heart before now, and we believe that the same sustaining element will enable him to persevere to the end.

The fifth volume carries the vocabulary from *Flaccus* to *Hearth*. It contains 15,555 author-titles, referring to 5,755 volumes and 12,596 pamphlets, and 42,196 subject-titles referring to books and journals. The number of pages is 1,055. Probably not more than one third of the work, and very likely less than that, has now been completed; but, when we remember that the first volume did not appear until the year 1880, the hope seems fairly warranted that the task may be finished during the next decade. It will then stand as an enduring monument of what devotion can accomplish when associated with such an enlightened policy as the Government has pursued in this instance.

MINOR PARAGRAPHS.

A NEW ENGLISH MONTHLY JOURNAL.

The first number of the "Medical Chronicle," published in Manchester, has reached us, and it is a pleasure to say that both its contents and its general appearance are admirable. Not long ago we informed our readers that the publication of the "Chronicle" had been announced, and we then gave a list of the distinguished gentlemen under whose management it was to be issued. The initial number is in the form of a large octavo, of one hundred and twenty pages, and contains the following original contributions: "On Tests for Albumin in the Urine—New and Old," by Dr. William Roberts; "The Pathology of the Lung Complications in Diabetes," by Dr. Julius Dreschfeld; "The Treatment of Dupuytren's Contraction of the Fingers," by Mr. James Hardie; "Surgical Drainage: a New Method of Subcutaneous Drainage and Irrigation," by Mr. George J. Robertson; and "Some Fatal Cases of Icterus Neonatorum," by Dr. Henry Ashby. In addition, there are classified abstracts of a very creditable character.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 14, 1884:

DISEASES.	Week ending Oct. 7.		Week ending Oct. 14.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	1	1	0	0
Typhoid Fever.....	48	12	42	13
Scarlet Fever.....	36	3	39	5
Cerebro-spinal meningitis....	2	3	2	2
Measles.....	19	5	6	6
Diphtheria.....	40	19	45	29
Small-pox.....	0	0	1	0

The American Academy of Medicine will hold its ninth annual meeting in Baltimore, at the Hopkins Hall of the Johns Hopkins University, on Tuesday and Wednesday, October 28th and 29th. Papers are announced as follows: The Relation of the Medical Colleges to Preliminary Education, by Dr. Peter D. Keyser, of Philadelphia; The Examination of Applicants for License to Practice, a Means of raising the Standard of Medical Education, by Dr. Edward Jackson, of Philadelphia; The Role of Bacteria in Infectious Diseases, by Dr. Henry O. Marcy, of Boston; The Trade Aspect of Medicine, by Dr. Albert H. Gibson, of the navy; The Induction Coil, its Varieties and the Differential Indications for their Use, by Dr. A. D. Rockwell, of New York; Differentiation the Test of Civilization: the Specialist and his Education (the President's Address), by Dr. Benjamin Lee, of Philadelphia; The Teachings derived from Observations in 137 Abdominal Sections, by Dr. R. Stansbury Sutton, of Pittsburgh, Pa.; Some Comparative Results of Treatment of Chronic Articular Osteitis of the Hip, by Dr. Virgil P. Gibney, of New York; The Place of the Physician in Literature, by Dr. Charles C. Bombaugh, of Baltimore; The Aim in Treatment of Angular Curvature of the Spine, by Dr. T. M. Ludlow Chrystie, of New York; Physiology in its More Public Relations, by Dr. Nathan Allen, of Lowell, Mass.; Statistics of Glaucoma, by Dr. H. Knapp, of New York; Specialties and their Relation to the Medical Profession, by Dr. L. Duncan Bulkley, of New York; Report on Laws regulating the Practice of Medicine in the United States and Canada, by Dr. R. J. Dunglison, of Philadelphia, and Dr. Henry O. Marcy, of Boston.

The Reception to Dr. W. S. Playfair, of London, given by Dr. Emmet, on Friday evening, the 26th of last month, is memorable on more than one account. In the first place, more representative men were gathered together from the profession in New York and the vicinity than are often to be seen, and, in the next place, the gathering was more truly of the best men in our ranks than is often met with. This is to be accounted for partly by reason of Dr. Emmet's ample accommodations, but chiefly, we are persuaded, on account of the spontaneous feeling of fellowship with a man who, like Dr. Playfair, has had the courage and the honesty to uphold the actual basis of facts upon which certain prominent features of American gynecology are based. At all events, the occasion was a memorable one, and seemed to be of the sort that ought to cement together with added force the two races that are of one blood.

Photographing the Larynx.—We have been shown a number of the photographs of the larynx that were exhibited in the Section of Laryngology at the Copenhagen meeting of the International Medical Congress, by Dr. Thomas R. French, of Brooklyn. From the striking clearness of these pictures, taken in connection with the fact that the process is applicable in the

cases of untrained patients, it must be said that Dr. French has made a distinct advance in the demonstration and recording of laryngeal difficulties.

The Alleged Maltreatment of Lunatics in Canada has been made the subject of a published report by Dr. D. Mack Tuke, special reference being had to the Province of Quebec. It is said that a Government inquiry will be instituted in consequence.

"Happy Thoughts" seems to have been the model after which the "Medical Times and Gazette" fashioned the first of a series of "Skeleton Introductory Addresses," and the writer imitates Mr. Burnand's style right cleverly.

The next International Congress of Otolology, according to our French exchanges, will be held at Brussels, in 1888.

The State Idiot Asylum at Syracuse.—We learn that Dr. James C. Carson, of the Institution for the Deaf and Dumb, in this city, has been appointed superintendent of the asylum.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 5, 1884, to October 11, 1884:*

CLEMENTS, B. A., Major and Surgeon. In addition to present duties, to take charge of the office of the Medical Director of the Department during the temporary absence of that officer. Par. 1, S. O. 195, Department of the Missouri, September 29, 1884.

HAPPERSETT, JOHN C. G., Major and Surgeon. Will be relieved from duty in the Department of the East, and ordered for duty at Willet's Point, New York.

WOODEUFF, EZRA, Captain and Assistant Surgeon. Granted leave of absence for four months. S. O. 235, A. G. O., October 7, 1884.

CRONKHIRE, HENRY M., Captain and Assistant Surgeon. Assigned to duty as Post Surgeon, Fort Reno, Indian Territory. S. O. 197, Department of the Missouri, October 2, 1884.

LORENG, LEONARD Y., Captain and Assistant Surgeon. From Department of the East to Department of California.

HAEVEY, PHILIP F., Captain and Assistant Surgeon. From Department of Dakota to duty in Attending Surgeon's office, Washington, D. C., relieving Robert W. Shufeldt, Captain and Assistant Surgeon, who, on being relieved, will report to commanding general, Department of the Missouri, for duty. S. O. 237, A. G. O., October 9, 1884.

POWELL, J. L., Captain and Assistant Surgeon. Granted leave of absence for one month on surgeon's certificate of disability.

SPENCER, WILLIAM G., Captain and Assistant Surgeon. Granted leave of absence for one month. S. O. 204, Headquarters Department of the East, October 8, 1884.

MC CREERY GEORGE, First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Meade, Dakota Territory. S. O. 115, Headquarters Department of Dakota, October 6, 1884.

TAYLOR, A. W., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Omaha, Neb. Par. 3, S. O. 87, Headquarters Department of the Platte, October 3, 1884.

BLACK, C. S., First Lieutenant and Assistant Surgeon. Granted leave of absence for fifteen days, to take effect this date. Par. 3, S. O. 131, Department of Texas, September 29, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending October 11, 1884:*

LIPPINCOTT, G. C., Passed Assistant Surgeon. Granted sick leave, October 4, 1884.

WHITING, ROBERT, Passed Assistant Surgeon. Ordered to the Naval Hospital, New York, October 6, 1884.

BROWN, S. A., Passed Assistant Surgeon. Resignation accepted, October 7, 1884.

BRUSH, GEORGE R., Surgeon. Detached from the Vandalia and placed on waiting orders, October 8, 1884.

CRAIG, THOMAS C., Passed Assistant Surgeon. Detached from the Vandalia and placed on waiting orders, October 8, 1884.

AYRES, JOSEPH G. Leave of absence for one month, October 10, 1884.

OBERLY, A. S., Surgeon. Ordered to the Naval Hospital, Portsmouth, N. H., October 10, 1884.

CLEBORNE, C. J., Medical Inspector. Detached from duty at Portsmouth, N. H., and placed on waiting orders, October 10, 1884.

STEELE, JOHN W., Passed Assistant Surgeon. Detached from the Brooklyn and placed on waiting orders, October 10, 1884.

BOYD, JOHN C., Passed Assistant Surgeon. Assigned to duty at Navy Yard, Washington, D. C., October 10, 1884.

A Medical Centenarian.—It is said that Dr. C. C. Graham, of Louisville, completed the age of one hundred years on the 10th inst.

Society Meetings for the Coming Week:

MONDAY, *October 20th:* New York County Medical Association; Medico-Chirurgical Society of German Physicians; Roman Medical Society (private).

TUESDAY, *October 21st:* New York Academy of Medicine (Section in Theory and Practice of Medicine); Medical Societies of the Counties of Kings and Westchester, N. Y., and Hunterdon, N. J.; New York Obstetrical Society (private); Ogdensburg, N. Y., Medical Association.

WEDNESDAY, *October 22d:* American Association for the Cure of Inebriates (New York); New York Pathological Society; American Microscopical Society of the City of New York.

THURSDAY, *October 23d:* New York Academy of Medicine (Section in Obstetrics and Diseases of Women and Children); Harlem Medical Association of the City of New York.

FRIDAY, *October 24th:* New York Clinical Society (private); New York Society of German Physicians (private); Yorkville Medical Association (private).

SATURDAY, *October 25th:* New York Medical and Surgical Society (private).

Proceedings of Societies.

BROOKLYN PATHOLOGICAL SOCIETY.

Meeting of September 25, 1884.

The President, Dr. B. F. WESTBROOK, in the chair;
Dr. A. H. P. LEUF, Secretary.

Cystic Tumor of the Uterus; Rupture of a Cyst; Death from Shock.—Dr. GEORGE D. HOLSTON read the following:

The tumor which I present was taken from a patient who died last March, aged forty-two years. Her clinical history, briefly stated, is as follows: In 1868 she had a violent flooding, and an examination revealed a fibroid tumor connected with the uterus. In 1869 she had a severe inflammation of the bowels, which inflammation also seemed to involve the tissues around the tumor. She convalesced from this, so that she was able to move about, and went South. Subcutaneous injections of ergot were given for a period extending over several years, without any satisfactory result. For many years she menstruated regu-

larly, sometimes losing considerable blood. In the autumn of 1882 she had a profuse hemorrhage, and an examination at that time revealed a polypus hanging through the os. In the autumn and winter of 1883 her general health was remarkably good. On the day of her death, after walking up a flight of stairs, she was suddenly seized with a severe pain over the region of the tumor, and a few minutes after expired. She had never had any children, or any miscarriages.

Autopsy, held two days after death.—The head was not opened. The thorax presented a marked bulging on the right side, the left side being flattened. On opening the abdomen, a considerable quantity of grayish purulent fluid was found. The heart, lungs, liver, kidneys, and spleen appeared anæmic; otherwise nothing abnormal was observed in them. A large tumor occupied the right iliac region, extending across to the left and upward, and causing considerable displacement of the abdominal viscera. The tumor was firmly bound to the walls of the abdomen and to the intestines by strong adhesions. Of the uterus, nothing but the cervix could be discovered, with a polypus protruding through it. The tumors, uterus, bladder, and rectum were removed together, and weighed eleven pounds. On cutting into the mass, it was found that several of the tumors had undergone cystic degeneration. A perforation was found in the thin wall of one of the cysts, which had permitted of the discharge of its contents into the peritoneal cavity.

The cause of the patient's death was shock. The exertion which she made had ruptured one of the cysts, the contents of which discharged into the peritoneal cavity.

Subperitoneal Uterine Fibro-cystic Tumor; Rupture of a Cyst; Death from Shock.—Dr. DAVID MYERLE read the following:

Through the courtesy of Dr. Cornelius Olcott, I present a specimen of pelvic tumor with the following history:

Mrs. B., aged twenty-six, married eight years; had always had good health prior to March last, when for the first time her menses ceased. During the succeeding months she had other presumptive evidences of pregnancy, with no unusual distress until the middle of June, when a neighboring homœopath was called, and, finding more abdominal distension than could be accounted for by pregnancy, proposed, after consultation, to aspirate. The procedure being objected to by the husband of the patient, Dr. Olcott was requested to assume charge of the case, and ascertained that the over-distension was due to an immense amount of fecal accumulation, obscuring all abdominal evidences of pregnancy. The loaded colon could be felt extending to and under the margin of the ribs. Repeated injections and digital assistance were required to dislodge the impaction, which proved to be made up largely of strawberry-seeds.

There could now be detected in the right iliac fossa, corresponding to the location of the broad ligament, an ovoid tumor, extremely sensitive, and presumed, by reason of the history of previous pelvic distress elicited from the patient, to be an inflammatory exudate. Vaginal examination revealed the same resisting mass filling Douglas's *cul-de-sac*. With the aid of anodynes, the patient was kept comfortable. Much difficulty was repeatedly experienced, however, in freeing the intestine of fecal accumulations from time to time; the nodular collections were readily discoverable, obstructing the descending colon. On one or two occasions the patient had voluntary evacuations. The evidences of pregnancy were at the time quite conclusive.

July 20th.—The heart's action became alarmingly weak, but responded well to ammonia and digitalis.

24th.—I was hurriedly summoned, and told that miscarriage was threatening. I had much difficulty in making a satisfactory vaginal examination, owing to the extreme pain the slightest

pressure occasioned. The os was well dilated, and the foetus was soon expelled. The placenta followed within a reasonable time, and appeared intact. The patient's condition improved markedly for a few days until August 3d, when, in the absence of Dr. Olcott, I was hastily called. I found the heart's action extremely feeble, the extremities cold, but the intellect clear. Resort to vigorous stimulation failed to avert death, which occurred at 6 p. m.

Post-mortem, twenty-one hours and a half after death, by Dr. J. H. Hunt and Dr. Myerle.—The abdomen was tense and distended, and there was a hard, resisting tumor in the right iliac fossa, smooth and ovoid, its position corresponding to the situation of the Fallopian tube. The lungs were perfectly normal except upward displacement. The heart was normal and contracted. The diaphragm was forced up to the fourth interspace on the right side, and on the left side to the third space, its concavity being occupied by the stomach (which was healthy) on the left side and by the liver (also normal) on the right side. The spleen was congested. The peritoneum was neither adherent, thickened, nor congested. The intestines were healthy; there were some fecal accumulations in the descending colon. The kidneys were normal in position. The capsule of the right one was adherent, and milary nodules were scattered over its surface. The organ was much enlarged, measuring 5 x 3 inches. An abscess was found involving almost all of the pelvis and the pyramidal portion of the organ. The left kidney was large and white; the capsule was not adherent (chronic desquamative nephritis). There were no tubercles. The uterus was considerably enlarged, its external measurements being 3½ x 3½ inches, and it readily admitted a finger into its cavity. There was found growing from the right side a tumor about 5 inches in diameter, and on the left side there were several small growths, all hard and resisting. That upon the right projected forward, forcing out the abdominal wall and extending backward so as to occupy the sacral region. The Fallopian tube rested upon its anterior surface. The largest of the tumors on the opposite side was of about one quarter the size of that on the right. The sigmoid flexure was impinged upon by the growth. On section of the uterus, a clotted mass was found adhering to its inner wall, appearing very like a piece of adherent placenta. On section of the tumor, it seemed evidently made up of fibrous tissue. The diagnosis was subperitoneal uterine fibroid. The cause of death was shock, due to rupture of a cyst upon the posterior aspect of the largest growth and the escape of its contents into the peritoneal cavity.

Specimens of Pelvic Tumors of various kinds were presented by the Curator, Dr. J. H. HUNT, in behalf of Dr. CHARLES JEWETT, Dr. N. B. SIZER, and Dr. G. G. HOPKINS.

Polycystic Ovarian Tumor; Removal; Recovery.—Dr. WALTER J. CORCORAN read the following:

Mrs. K., aged thirty-five, a native of Ireland, the mother of six children, the youngest of which was born fifteen months ago, was admitted to St. Mary's Hospital May 8, 1884. About two years previous to her admission she noticed a swelling in her left side. Being pregnant at the time, she thought the abdomen was larger than it should be for the supposed stage of pregnancy (about four months), and consulted a physician, who told her she had a tumor. Shortly after she felt life, and thought the doctor was mistaken. She went on to term and was delivered, after normal labor, of a healthy child, but the swelling in the left side still remained, and the physician confirmed his former diagnosis. She had had mild symptoms of peritonitis on several occasions. Some time after delivery, and four months prior to operation, she came to St. Mary's for examination. A tumor was found on the left side. It was freely movable, and could be grasped between the two hands and moved to the

other side of the abdomen. During the last six months the tumor has grown quite rapidly, but, except from its size and weight, has occasioned her very little pain or inconvenience. Her menstrual history has been normal. The steady, and of late rapid, increase in the size of the tumor, with depreciation of her general health, determined her to submit to operation for its removal.

Operation, May 10th.—After the usual incision through the abdominal wall and peritoneum had exposed the cyst, a trocar and cannula were introduced and about four quarts of thick, greenish fluid withdrawn, when the flow stopped and it was found that the tumor was polycystic. After one or two small cysts were evacuated another was tapped, which yielded about two quarts of fluid. The remaining portion of the tumor was found to be solid, too large to be drawn through the incision, and held by membranous adhesions. The abdominal incision was enlarged and the adhesions were broken down. Two of them, especially strong and vascular, required division with scissors after preliminary ligation with catgut. The adhesion to the bladder was especially troublesome, and a sound, introduced as a guide to its position, was plainly seen covered, but by a very thin layer of tissue, presumably only the mucous coat. The tumor was found attached to and involving the left ovary, tube, and broad ligament. The pedicle was formed by transfixing the broad ligament and ligating close to the uterus with strong silk. The tumor was then removed, and the stump was seared with the galvanic cautery and drawn down to the lower angle of the wound. The cavity was carefully sponged out, and several bleeding-points were secured with catgut ligatures. The silver-wire sutures were placed in the abdominal wound, the peritoneum was again inspected, another ligature was thrown around the pedicle, which was dropped into the cavity, and the wound was closed. The dressing consisted of a strip of carbolized lint over the sutures, covered by a layer of absorbent cotton and a thick pad of marine lint, secured with a binder.

The patient bore the operation fairly well, and passed a quiet but sleepless night. The subsequent history presents nothing of interest, except that recovery was somewhat delayed by a mild cystitis, which yielded readily when the bladder was washed out with hot water and borax. The sutures were removed on the tenth day, and the patient was transferred to her own room on the sixteenth.

Cysto-sarcoma of the Uterus; Peritonitis; Death.—Dr. CORCORAN read the history of this case also, as follows:

Ellen C., aged thirty-seven, Irish, single, was admitted to St. Mary's General Hospital, August 19, 1884, with the following history: Abdominal enlargement began eleven years ago, at which time she had menorrhagia. There never was sufficient pain to cause distress. Soon after the enlargement of the abdomen, oedema of the feet appeared and was more prominent in the right one, though now about the same in both. During ten years the disease made little progress. About one year ago the menses were absent for about five months, and then became regular up to March of this year, since which time there has been no menstrual flow. About the same time the abdomen began to increase rapidly in size until, in June, it was so large and occasioned so much dyspnoea that tapping was necessary for her relief. She says that nineteen quarts of clear fluid were drawn off, and that then a hard tumor of about the size of a cocoanut remained. The relief obtained was brief. The abdomen began to fill up again, and is now larger than in June. She has but little rest, and it is impossible for her to lie down on account of the interference with respiration.

Examination of the urine revealed nothing. The patient appeared extremely wretched and feeble. She moved with difficulty, and was greatly distressed in breathing. The photograph,

by Mr. Van Cott, shows the appearance of the abdomen better than any description. From the symmetry and peculiar appearance of the abdomen, the marked fluctuation, and the history, it was evident that the bulk of the fluid was a peritoneal effusion. The tumor could not be made out. Digital examination by the vagina gave no information. As evacuation of the fluid was imperative, it was deemed best to effect this by an exploratory incision, and then, after examination, if possible, to remove the tumor. Dr. John Byrne believed the tumor would be found to be malignant, as uterine and ovarian tumors, accompanied by peritoneal effusion, with oedema of the limbs, were generally, in his experience, malignant. The late rapid development of the symptoms after ten years of slow progress tended to show a malignant development in what may have been originally a benign growth. The gravity of her case was laid before the patient, and she asked for the operation as her only chance. She was put on preparatory treatment and the operation performed.

Operation, August 30th.—An incision was made in the median line down to the peritoneum. A large trocar was then used and twenty-seven quarts of clear, straw-colored fluid were removed. A large tumor was then found, in general hard, but with several points giving fluctuation. It was a continuation of the uterus and free on its upper and lateral borders. It was adherent to the left Fallopian tube. The incision was enlarged. Two cysts were punctured, which did not materially diminish the size of the tumor, which was with difficulty drawn out. The utero-ovarian vessels were ligated. A few turns of rubber tubing were used as a tourniquet, and the tumor was removed at the level of the internal os uteri. Two or three vessels, which had escaped the tourniquet, occasioned considerable hemorrhage, but were finally secured by ligature. The cervix was transfixed by a needle carrying a double ligature of strong silk, and in this way the stump was securely ligated. The rubber tourniquet was removed, the stump seared with the galvanic cautery, and another silk ligature tied around it. As these ligatures included so much tissue, it was deemed best to use a clamp as an additional safeguard against hemorrhage, so that the pedicle was treated by the extra-peritoneal method. The wound was closed and dressed as in the previous case.

The patient bore the operation well, and was removed to bed in fairly good condition. For the first twenty-four hours her condition was as favorable as could be expected, but then the abdomen became tympanitic, the temperature rose gradually, and she died on the fifth day. She had no pain whatever. Her temperature did not run up high till within twenty-four hours of her death, when it was 105° F.

The following is the report of the autopsy, by the pathologist, Dr. Leif: Body partly wasted. Abdominal wound extending up from the pubes to near the umbilicus. A clamp holding the pedicle of the tumor was found in the lower part of the wound. The clamp was imbedded in a transverse fold of the abdominal parietes due to over-distension of the intestines with gas. The lungs were emphysematous and a little hypostatically congested and oedematous. The heart was soft and flabby, and all its cavities were filled with post-mortem clots. The liver was very fatty, soft, and friable, with very rotund margins. Its capsule was very thick. The spleen had a very thick capsule, and was firm and light in color. The pancreas was normal. The stomach and intestines were much distended with gas. The kidneys were soft, but healthy. The peritoneum below the umbilicus was very thick and inflamed, and had a greenish hue. This greenish discoloration was very sharply defined by a distinct line extending transversely completely across the anterior abdominal wall at the level of the umbilicus. All below this was greenish, and above it normal in appearance. The pedicle consisted of the cervix uteri stretched so as to measure over

5 cm. in length. The wound had partly united. It had a healthy appearance.

Dr. J. H. H. BURGE expressed it as his opinion that it might have been well to remove a portion of the superfluous part of the anterior abdominal wall.

Dr. F. W. WUNDERLICH remarked that Hegar and Kaltenbach, who had had the best results, prevented many deaths from peritonitis by sewing the visceral peritoneum attached to the stump to the parietal layer of the anterior abdominal wall at the edge of the wound. Thus the peritoneal cavity was hermetically sealed. The elastic ligature was used in these cases. The exposed surface of the stump was treated with the chloride of zinc. The plan of treatment was only resorted to in uterine excisions and not in ovariectomies. The great object in this plan of treatment was to obtain early and complete union between the peritoneum of the stump and that of the edge of the wound.

Tubal Pregnancy; Rupture of the Sac; Death.—Dr. A. H. P. LEFF presented the following history of the case:

The patient was a young lady, well nourished and of fine physique, and married not quite eleven months. She was but twenty years of age, and born in this country. On Sunday even-

(August 21st) Dr. J. E. Clark was called in to see her. He found her lying upon her back on the floor in the basement of the house, with her lower extremities a little abducted, and complaining of total inability to move. She had intense abdominal pain; the onset had been quite sudden. There was decided nausea, with intense thirst. The pain was most marked in the right iliac region. She had never been sick before. She had spent all the day at some country place, and had eaten very freely of melons and grapes without, however, having swallowed any seeds, but the preceding week she had swallowed many seeds while engaged in eating grapes. She had failed to menstruate at her last two periods. The doctor noticed a slight bloody discharge from her vagina upon inspection, and was told that the patient had had it for the last two or three weeks, but that it had always been very slight. Her abdomen was also greatly distended, and her bowels had moved but sluggishly the last few weeks. An enema of soap, water, and castor-oil was ordered and given, and followed by active results. Her pulse was feeble and beat 120 times a minute. The sulphate of morphia was administered hypodermically in the form of Magendie's solution, μvii being the dose. The patient was advised to drink warm water, but could not swallow. Later in the evening she vomited very freely, but slept well during the night. The doctor saw her several times the next day, and found the pains returning with renewed vigor and simulating uterine pains. He prognosticated an abortion. During the afternoon he made a vaginal examination and found the uterus inactive, but low down and with an elongated cervix and a slightly enlarged body; μvii of Magendie's solution were again given hypodermically that night. The following morning she felt very uncomfortable, and received μv once more. The day previous hot fomentations of hops had been applied to her abdomen, while on this day flaxseed poultices were used instead. Early in the evening of this day (forty-eight hours after the onset of marked symptoms) her pains became very severe, and were referred to her bladder. Persistent efforts to urinate proved ineffectual. μx of Magendie's solution were again given, and an hour later she felt very comfortable and cheerful, and laughed. At one o'clock that night the doctor was hastily summoned to the bedside of the patient. He found her breathing irregular, intermissions occurring at every fifth respiration. They averaged from 25 to 30 a minute. Her pulse was very small, and beat 180 times a minute. She was almost completely comatose, and could hardly be roused at all. Her pupils were very much contracted. Dr. A. Ross Matheson was hastily sent for, and, upon consultation with him, the patient received

hypodermically $\frac{1}{4}$ gr. of extract of belladonna and μx of tincture of digitalis. An hour later half of this quantity was given again and in the same way. Her pulse became fuller, and went down to 120. Her respirations were 42. She died two hours later, at 6 A. M., being about sixty hours after the onset.

I made the autopsy thirty-four hours after death, in the presence of Dr. J. E. Clark, Dr. A. Ross Matheson, and Dr. H. Tut-hill Halleck. She was short and stout, having a remarkably well-formed figure and a very pale skin. Her complexion was dark. The adipose tissue of her anterior abdominal wall was fully 7 or 8 cm. thick. All her viscera were extremely pale. The lungs and heart were normal, except that the latter contained firmly clotted and decolorized blood in all its cavities. Elsewhere the blood was in a fluid state in its normal receptacles. The liver was slightly fatty. The spleen was remarkably pale, bloodless, and soft. The pancreas was pale and soft, and its peripheral lobules had undergone fatty metamorphosis. The stomach was normal, as was also the rest of the *primæ viæ*. Both kidneys were healthy but pale. Upon opening the abdomen, a sero-sanguineous fluid escaped amounting to about 5 litre. A large blood-clot was found in the lower part of the abdomen, resting upon and mingling with the intestines. Its upper margin formed a moderately straight line, extending transversely across the abdomen up to within 2 cm. of the umbilicus. Imbedded in it, and adherent to it by recent inflammatory adhesions, were loops of the ileum, the side of the cæcum, and the folds of the sigmoid flexure. The pelvic cavity was filled with the clot, and the uterus imbedded in and adherent to it. A sac fully 6 cm. in diameter was discovered connected with the right Fallopian tube at its middle. It contained the residual portion of a large blood-clot, and, after this had been removed, the unruptured amniotic sac was exposed, containing an embryo measuring about 2 cm. in length. The rupture had taken place at that portion of the surface of the sac facing the left lumbar region. The uterus was but slightly enlarged and very pale. Within it was found a false, thin decidua half exfoliated and red in color.

This specimen has not been presented merely as a curiosity to be gazed upon, but also for the purpose of eliciting a thorough practical discussion of the clinical aspects of the case, and especially with reference to the diagnosis and treatment of similar cases. I myself do not see how a diagnosis could have been made in this case except by some one specially interested in the class of subjects to which it belonged, and then, very likely, only at a time when such a person was doing a good deal of thinking on that subject. Guided largely by the teachings of Professor Jewett, I would express it as my opinion that the proper thing to do in case a reasonably confident diagnosis had been made would be to open the abdominal cavity, and, if need be, make a counter-opening in the *cul-de-sac* of Douglas to insure good drainage. This might be facilitated by elevating the shoulders and chest of the patient. Of course, the tying of the bleeding vessels and excision of the abnormal mass, with a thorough cleansing of the abdominal cavity, are understood. Is it not best in cases of doubtful diagnosis, when a patient seems to be in serious danger and has symptoms of internal hemorrhage, most likely abdominal, to make an exploratory abdominal incision for diagnostic purposes?

Dr. J. E. CLARK stated that the patient from whom the specimen had been removed had very thick abdominal walls, which made it impossible to feel the tumor.

Dr. WILLIAM MADDERN thought it much more difficult to diagnose cases in which the hemorrhage was slow than those in which it was rapid. He had seen three cases. In one of them the condition was suspected, but no one had the courage to operate.

Dr. LEUF stated that the clot in the case he had reported was very firm and quite fibrinous in some places, while in others it bore every evidence of having recently formed. This was good evidence of the hemorrhage having been gradual and persistent.

Syphilitic Brain Disease.—Dr. LUCY M. HALL read a paper embodying the history of a case. [See p. 430.]

Syphilitic Disease of the Finger; Amputation.—Dr. HALL also presented the following case:

L. S., aged twenty-six, a widow, intemperate and lowly, was born in Scotland. Her father and one sister died of heart disease; her mother is living, and healthy. Her first child died of hydrocephalus at the age of four months. One year ago she aborted at the fourth month of pregnancy. She denied ever having had venereal disease.

February 3d, 1882.—Admitted to the hospital. Pulse, temperature, and respiration normal. Tongue clean, appetite good, bowels constipated. Menses scanty and irregular. General condition not good. She said that her finger began to be sore five years ago, that she had been treated by various physicians since that time, but that there had been no improvement. At the time of her admission to the hospital the finger (the index of left hand) was diseased nearly to the second joint. It was very painful, the pain passing up the arm and shoulder and causing general disturbance of the system. The finger was flattened upon the dorsal and palmar surfaces, and a good deal enlarged, giving it a broad, flat appearance. It was covered at the end and upon the dorsal surface with various pits and projections, was dry and scaly, and had a dark-purple color. The general appearance was so malignant, and the history of former treatments so discouraging, that amputation was decided upon. This decision was entirely in accord with the wishes of the patient.

4th.—The patient was anesthetized and the finger amputated a little below the second joint. Antiseptic precautions were employed during the operation and in the dressings. The wound did not heal well; there was some sloughing, and the general condition of the patient was unsatisfactory. She finally admitted that she had suffered from chronic sore throat, and that she had been troubled with nocturnal headaches and rheumatism. A second amputation was decided upon, the same precautions being observed as in the first operation. A short stump, with a well-fitting flap, was secured, and the patient was immediately placed upon two-grain doses of iodide of potassium. The healing of the wound was now rapid and satisfactory, being complete in two weeks.

The patient afterward suffered severely from syphilitic rheumatism and neuralgia, which finally yielded to antisyphilitic treatment.

Dr. F. W. ROCKWELL said that Dr. Hall's first case exemplified in a marked degree one clinical point in all these cases of nervous syphilis, whether "explosive" or more chronic in their forms, and that was that the tolerance of the stomach for large doses of the potassic iodide was the pivot upon which the outcome of the case often turned. Of course, many cases were suddenly fatal; but, where time for treatment remained, the surgeon was at the mercy of the patient's stomach. He had had two cases recently which illustrated this point. The first was that of a young woman who came to him at St. John's Hospital, exhibiting all the symptoms of cerebral syphilis, which she said had only been developing for about a week. She was then excitable, crying constantly while telling her story, was aphasic, had a dilated pupil on the right side, and slight left hemiplegia and other nervous phenomena—such as patchy anæsthesias, etc.—were present. She was urged to enter the hospital at once and put herself under treatment, but declined until

three days afterward. During that time she had so far lost her powers as to be unable to walk one block to the hospital from the cars, spoke incoherently and almost unintelligibly, and was comatose in a few days. Under rapidly increased doses of iodide of potassium, improvement was beginning, when she developed an intolerance for the drug in any form, and steadily failed, dying comatose and paraplegic in a short time. On entering the hospital she had admitted infection two or three years previous.

The second case was that of a young man who, six years after a primary sore and almost trivial secondary symptoms, began to manifest anomalous nervous disturbances and severe mercuriana. After a few days of prodromes, he was suddenly seized with complete paraplegia, rectal and vesical paralysis, nocturnal delirium, and intense cephalalgia, aphasia, mydriasis, etc., as in the first case. Potassic iodide was given in gramme doses, and rapidly pushed till thirty grammes per diem were given in four doses. Not until ten- or fifteen-gramme doses were reached did any improvement manifest itself, and then steady diminution of all the symptoms began. In three months the patient began to resume his employment, though some ataxic phenomena persisted for months, and increased whenever any diminution in the daily dose was attempted. Nothing but the unusual tolerance of the stomach for the drug had in this instance saved the patient's life, and the speaker was in the habit of basing his prognosis in these cases largely on the power of the patient to retain and absorb the huge doses necessary for a cure.

CHICAGO MEDICAL SOCIETY.

Meeting of October 6, 1884.

The President, Dr. D. A. K. STEELE, in the chair;

Dr. LISTON H. MONTGOMERY, Secretary.

National Sanitation.—Dr. JOHN BARTLETT, chairman of the Committee on National Sanitation, reported that, while the committee had agreed on the substance of the proposed resolutions to be submitted for presentation to Congress, the resolutions were not in shape to report to the society, although signed by most of the members. He therefore asked for further time to consider the matter, which was accorded.

Dr. JOHN H. RATCH, secretary of the Illinois State Board of Health, had read the resolutions prepared by the committee, and, as he had been invited by one of its members, he would speak of their importance, and that of national co-operation with State and municipal governments in arresting the spread of epidemics. Matters should be so arranged that there would be concert of action in all the municipal and State boards with a national health organization. The National Government should have control of Inter-State quarantine. The trouble all arose out of inefficient maritime quarantine. Illinois was specially interested in this, from the St. Lawrence River to the Rio Grande, and from the Atlantic Ocean to the Pacific Ocean, for this State paid more internal revenue tax than any other State in the Union—New York not excepted. Cholera might reach Montreal or Quebec and be brought to this city and State over the Grand Trunk, the Michigan Central, or the Michigan Southern Railway. We had authority to stop the trains at the State line only, and prevent their entering the State of Illinois. New York controlled that port exclusively, and Illinois had no authority to interfere, while her interest in keeping out diseases was just as great as that of New York. The Illinois Board of Health was prepared to prevent the entry of infectious and contagious diseases, no matter what contingency might arise, but it would be better if she could depend upon the aid of her sister States, which were equally interested. Two thirds of the immi-

grants coming to this country arrived at the port of New York. The Emigrant Inspection Service carried on by the National Board of Health a few years ago, under the auspices of the National Government, was done at a cost of \$50,000, when some forty thousand emigrants or more were vaccinated on the trains, and there was no detention. The National Board of Health no longer existed except in name, the last Congress having cut off all appropriations; consequently we were not in so good a condition to ward off epidemics as we were three or four years ago. An endeavor to protect the States could not be well made, on account of inefficient maritime quarantine. The only resource we had at present to cope with these diseases was for the different States to act in good faith with each other. An illustration was cited by the speaker to prove his statement correct.

In 1878-'79, along the banks of the Mississippi and Ohio Rivers, epidemics prevailed. Since the organization of the Sanitary Council of States along these rivers, infectious diseases and all other diseases were much less prevalent. The speaker then recited the history of the National Board of Health, the inefficiency of our laws, etc., and cited further illustrations. How inadequate the surgeon of this port and the one at Cairo would be to cope with any form of epidemic that threatened an invasion in this State! Instead of this being only under the control of a State, it should be controlled by the National Government. Now was the time to prepare to secure legislation instead of waiting until after the occurrence of an epidemic, as had been done heretofore. Those who had charge of sanitary interests in the different States should study the causes of disease, and, through thorough co-operation with a national health bureau, we should be well prepared to protect ourselves against an invasion of cholera next year.

No one man could control the state of commerce satisfactorily, nor could this be done by one State alone; more States should be represented, and concert of action between all those in authority should prevail. The United States Treasury was entirely independent of States in this respect. A conference of the boards of health of the several States and territories would be held at St. Louis next week, having for its object the co-operation of all authorities for the purpose of controlling epidemic and contagious diseases. He thought that some plan would be evolved that would prove satisfactory to all, and do away with the jealousies that had hampered the action of the national health bureau. The general feeling prevailed that we were going to have cholera in this country next year, and now was the time to prepare for it, as the resolutions call for.

Dr. J. H. HOLLISTER said that, as a member of the committee, he should decline to attempt to instruct Congress as to its duties in the matter, but thought that a memorial presented by this society would be the better mode of procedure. If our memorial to Congress only asked for what was most wanted by the public, then we, as medical men, had done our part. It was a subject that took hold of common interests, and how to render efficient aid suitably but not unnecessarily was something upon which more wisdom can be gained by other methods than temporary discussion. He thought our wisest men should meet in conference and unite on some practical method, and then urge legislative action. He asked Dr. Rauch to what extent the States were moving in the direction of having State Boards of Health organized, and to what extent their authority reached. He was answered that Massachusetts, New Hampshire, Connecticut, New York, New Jersey, Maryland, West Virginia, Virginia, Indiana, Illinois, Michigan, Kentucky, Tennessee, Louisiana, Mississippi, Arkansas, Alabama, Iowa, Wisconsin, Minnesota, and Missouri each had its State Board of Health. Ohio, Pennsylvania, Maine, and Vermont had none; Lower Canada had none; but the Ontario Board of Health was

in good shape. The Michigan Board of Health was an advisory one; the Illinois Board of Health controlled quarantine, and could call on sheriffs and constables to obey her dictates. The boards of Missouri and Minnesota were nearly like ours. New York's board was partly like ours in authority. Indiana's was nearly like ours, only better, for there they had county boards of health. The boards of health of Maryland and Virginia were also very efficient.

Dr. L. H. MONTGOMERY alluded to the merits of the National Board of Health and the efficient services it had rendered in the past, and asked why it should not be sustained and appropriations made for it, on the same general principle that we should retain the services of any faithful servant that had been in our employ. He had spoken upon the subject to the representative of the Congressional district where he resided, and had been informed by the member that he would be glad to do his part and use his influence toward securing the granting of legislation for the establishment of some form of a national sanitary organization. The speaker was also assured by the honorable gentleman that he had been and was at present a friend of the National Board of Health. Regarding a "memorial to Congress," as suggested by Dr. Hollister, the resolutions had a clause providing for this, which had been very favorably considered. Indeed, if need be, we might go further, and have a petition transmitted simultaneously with the memorial, with an array of prominent names from all over the country, asking our national legislators to provide for the maintenance of such a board for Inter-State observation, etc., constituted by the appointment of some one scientific medical gentleman from each State and territory in the Union. Our representative on the National Board from this State was eminently well known, and should be kept there.

Dr. R. E. STARKWEATHER had hoped that the committee would be prepared to submit their resolutions this evening. He, as one of its members, indorsed every word they contained, even at the risk of their being (as possibly they were in one place) tautological. He hoped the committee would be able to have them ready before the close of the week.

Dr. RAUCH, in conclusion, stated that he intended to speak to some extent upon this subject at the meeting of the State boards of health to be held at St. Louis next week. A special meeting would probably be held at Washington in December of all the State sanitary boards, at which time this subject will receive special attention.

The society tendered a vote of thanks to Dr. Rauch for his address and the information given. The Committee on Resolutions was requested to meet immediately after the adjournment.

NEW YORK ACADEMY OF MEDICINE.

Meeting of October 2, 1884.

The President, FORDYCE BARKER, M. D., LL. D., in the chair.

The Three Tonsils: Some Practical Suggestions as to their Structure, Function, and Diseases, was the title of a paper read by Dr. F. H. BOZWORTH. The author said that, with regard to the three tonsils, he had for some time entertained certain views different from those usually expressed in medical literature. By the three tonsils he meant the two glandular masses found between the pillars of the fauces and that found in the vault of the pharynx, first recognized and described by William Hunter. The former were called the faucial tonsils and the latter the pharyngeal tonsil. The faucial tonsils were not, as generally described, covered by a fibrous sheath, nor were they necessarily almond-shaped, but of whatever shape any morbid process might have given them. The tonsil was not an

organ of the body in the sense that the liver or spleen constituted an organ, and therefore it had no special function to perform in the animal economy. Virtually there were no tonsils; the organ so-called did not exist in the healthy throat, but was the result of a morbid process. All mucous membranes were richly endowed with glands, and perhaps no portion of the mucous tract called for a greater amount of mucus in the performance of its function than the upper air-passages, and there we found the glands aggregated in masses. In a condition of health this aggregation of glands did not project prominently from the mucous membrane, nor was its existence easily demonstrable by inspection. But the mucous membrane of the upper air-tract was liable to repeated attacks of inflammation, especially in the young, and the tendency of a chronic inflammatory process was to develop hypertrophy in these glands. Dr. Bosworth considered that the only function of the masses of glands in question was to supply mucus or lubricating fluid.

The three tonsils were liable to the same diseased conditions. These might be considered under the following heads: Acute follicular, subacute, croupous, and diphtheritic inflammation, and hypertrophy. He did not believe that phlegmonous inflammation ever occurred in the tonsil; quinsy was rather a disease of the cellular tissue of the fauces than of the tonsils; it involved the areolar tissue, especially of the soft palate, in rare instances of the pharyngeal walls, and not the glands. He believed it to be usually due to the rheumatic habit. Within the past three years 133 cases had come under his observation—88 in males, and 45 in females. The oldest patient was aged sixty-nine years, and the youngest nine months. Of the entire number of cases, the phlegmon occurred in the soft palate in 115; in the pillars in 11; beneath the tonsil in 2, but in the tonsil proper in none. In a large number of instances quinsy was aborted by the administration of the salicylates, and when it did not have this effect, the medicine seemed to hasten suppuration. He gave a tablespoonful every two hours of a solution of three drachms of the salicylate of sodium in six ounces of water. He had also found the bicarbonate of sodium useful, as recommended by Dr. Barker, but not equally efficacious with the salicylate. If an abscess formed it should be treated as an abscess of any other portion of the body—incised.

Dr. Bosworth thought that in acute follicular amygdalitis there was a greater amount of constitutional disturbance than could be accounted for by the local affection, and he had been led to regard it as one of the essential fevers, liable to recurrence.

Hypertrophied tonsils gave rise to a train of symptoms mainly due to mechanical obstruction of the passages. The enlarged tonsil showed a tendency to subside at the age of puberty. It developed purely from a local morbid process, and was not the manifestation of a dyscrasia. Hypertrophy of the pharyngeal tonsil had been described by many writers as adenoid tumors or vegetations of the vault of the pharynx. If the hypertrophied tissue offered a mechanical obstruction it should be removed. Local medication, he believed, had no effect whatever in reducing genuine hypertrophy of the glands. It had been suggested that only a portion of the tonsil should be removed, but there was no more reason for this than there was for removing only a portion of a tumor developed elsewhere in the body. There was no danger from hæmorrhage. In children there was only a slight amount of bleeding, and if in the adult considerable hæmorrhage should arise from any mistake on the part of the operator, it could best be checked by the actual cautery. It would be found to come only from the nutrient artery, and on arterial hæmorrhage styptics had no effect.

Before calling upon the fellows of the Academy to discuss the paper, the PRESIDENT offered a few remarks concerning the

use of bicarbonate of sodium as a remedy for quinsy. He had been in the habit of seeing a few cases of this affection every year, and it had almost invariably gone on to suppuration, until, for some reason he could not now recall, he began the local application of the bicarbonate of sodium, and since then in most instances the disease had not gone on to suppuration.

Dr. DOUGLAS said there were a few things in the paper of the evening to which he would take exception, but with regard to most of the points made he would record his judgment in accordance with that of the author. He agreed with Dr. Bosworth that quinsy was one manifestation of the rheumatic, or rather of the gouty, diathesis. He had employed the bicarbonate of sodium in its treatment for many years, and had also given the ordinary remedies against the gout. He found a beneficial effect from a powder containing one per cent. of menthol and ninety-nine of sugar of milk. While the knife would surely remove the enlarged tonsil, he did not think it always necessary to resort to it, as the enlarged glands could be reduced in size by the continued use of a powder composed of common salt, camphor, chloride of ammonium, and sugar of milk.

Dr. F. H. HAMILTON was disposed to agree with the author, that the proper treatment for a hypertrophied tonsil was removal with the knife; still, he had observed that in young people the hypertrophied condition disappeared or became less of an obstruction as they attained to adult life. When the author said there was no danger from hæmorrhage, he probably did not refer to the acute or engorged stage, or to the hæmorrhagic diathesis. He thought as much of the gland should be removed as the knife would include; he knew of no reason why a part of it should be left behind.

Dr. A. JACOB believed the enlarged tonsil was amenable to no other treatment than removal with the knife. Astringent agents could have no effect in diminishing its size. In cases in which they seemed to have such an effect the true explanation was growth of the fauces or contraction of the hypertrophied tissue in the gland. Bleeding might occur from cutting away a portion of the soft palate with the tonsil—an accident which could not always be avoided. The best means for checking hæmorrhage was digital compression, and it might prove necessary to employ this an hour or more; in some cases, however, the hæmorrhage was thus checked almost immediately. He could not agree with Dr. Bosworth that acute follicular amygdalitis was an essential fever; he regarded it as a local disease. Some of the cases which had been considered instances of acute follicular inflammation he thought might have been instances of diphtheria without a well-marked diphtheritic membrane. It was a serious error to suppose that all patients suffering from diphtheria must necessarily die, and to look upon all those cases in which recovery took place as instances of some other form of throat affection. He laid stress upon this point, although it was somewhat foreign to the matter under discussion, because of its importance to the public health.

Dr. L. WEBER had not yet seen a case of phlegmonous inflammation around the tonsil which he could trace to the gouty habit. He had seen it most frequently in people of poor general health.

The PRESIDENT here remarked that at one time guaiacum was highly recommended in this throat affection, on the strength of its supposed relation to gout, but he had not found the remedy so beneficial as certain articles in the medical journals would have led him to anticipate.

Dr. A. C. POST thought the best way of getting rid of the enlarged tonsil was to remove it.

Dr. F. H. HAMILTON had best been able to check hæmorrhage by the external application of ice or snow to the throat.

Dr. FORTMIGHT had been able to abort some cases of quinsy by the administration of the tincture of aconite.

Dr. W. C. JARVIS again called attention to a distinction which he had before made between the soft and the hard enlarged tonsil. The former could be extirpated with the knife without danger from hæmorrhage. The latter, or indurated, or scirrhous enlarged tonsil, was syphilitic, and, when cut into, was liable to give rise to even fatal hæmorrhage. Here the cautery or the snare alone should be employed. He did not think any more of the tonsil should be removed than was really necessary; it probably performed the office of protecting the carotid artery in addition to lubricating the air-passages.

Dr. BRANDEIS was a little astonished at the views entertained by Dr. Bosworth concerning the function of the tonsils. He believed in the Darwinian theory of the survival of the fittest. The tonsils had survived some thousand years, and they doubtless had performed their function, whatever it might be. Still, a diseased tonsil might be worse than no tonsil at all, and it might become necessary to extirpate it. He then pointed out the advantages of the tonsil guillotine over the knife. He had always found some hæmorrhage after the operation in the young subject. He allowed the patient to sip a solution of tannic acid in case of bleeding. Quinsy had before been described as a peri-amygdalitis, but he could not agree that it was always an inflammation of the tonsillar capsule. He recommended the tincture of aconite and ammoniated tincture of guaiacum in its treatment if suppuration had not taken place.

Dr. J. L. CORNING had arrested severe hæmorrhage after amygdalotomy in one case by the use of his carotid compressor.

Dr. BOSWORTH, in closing the discussion, said he did not believe that astringents could have any effect in reducing the enlarged tonsil. As to hæmorrhage, it proved troublesome only in adults; in children there was only a little oozing. That amygdalotomy was not dangerous was evident from the fact that not a single fatal case had been recorded in medical literature. He would except those in which the carotid artery had been cut—an accident which could not befall a surgeon. Hæmorrhage was best checked by applying the cautery from above downward, thus avoiding cooling of the iron by the blood running down from above. He thought peri-amygdalitis a very good name for quinsy, but as to the tonsillar sheath always being involved, he did not recognize any such sheath as commonly understood by the term. As for the tonsils fulfilling the office for which they were destined, he had said in his paper that he considered them simply the result of a morbid process. They were not to be found in the normal throat.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of September 24, 1884.

The President, Dr. GEORGE F. SHRADY, in the chair.

Sarcoma of the Lung and Mediastinum.—Dr. VAN GIESEN presented a specimen of supposed primary cancer of the lung and mediastinum, for which he was indebted to Dr. French, from whom he had obtained the following history: The patient was forty-one years of age, a German woman, who was admitted to the hospital September 11, 1884. Over the upper lobe of the right lung there was entire absence of the respiratory murmur and of vocal fremitus. The respiratory sounds were unaltered by change of position. There was also complete dullness. The physical signs on the left side of the chest were normal. The patient was much emaciated. There was œdema of the left upper eyelid, but there was no œdema of the extremities. There were tympanites and dyspœa. There was cough

without expectoration, nausea without vomiting. There was no history of hereditary cancer. Death took place on the 16th. The brain was not examined. The pericardial sac contained eight ounces of clear serum. In the mediastinum and upper portion of the right lung there was a hard cancerous mass. The remainder of the lung was healthy, with the exception of a few adhesions at the base. The bronchial glands were enlarged, and the right bronchus was constricted to the size of a No. 8 English catheter. The kidneys and spleen were found to be normal; the liver was slightly fatty. Unfortunately, the uterus was not examined. A hasty microscopic examination of the diseased lung-tissue pointed to sarcoma, not to carcinoma.

This was the fourth or fifth similar case which the speaker had had the opportunity to see during the past three years, and he had found a feature of importance in the diagnosis to be absence of vocal fremitus. Usually, with condensation of the lung, we expected to find the vocal fremitus more or less exaggerated; but here we could readily account for its absence by the fact that the right bronchus was nearly closed. In one case, which Dr. Janeway had seen with him, this feature had been an aid in the diagnosis. With regard to the œdema of the left eye, this occurred in one of the other cases, and, as in this instance, it was on the same side as the diseased lung. He had tried to account for it on the supposition that the circulation on that side was obstructed by the enlarged glands.

Precocious Phagedenic Syphilides.—Dr. WYETH presented a patient, thirty-five years of age, a book-keeper and a German, who was admitted to Mount Sinai Hospital on the 11th of July, 1884. He had suffered from gonorrhœa several times, the last attack being eight months before his admission. Five weeks and a half prior to July 11th he had intercourse with a prostitute, and one week later observed a small blister at the base of the penis. He had not had intercourse for some weeks prior to this time. The blister remained of about the same size for ten days, when he again had intercourse, and a few days later the sore began to extend and to become very painful. On admission there was a large non-suppurating bubo at the base of the penis, the apex extending up the penis, one angle at the base extending on to the scrotum, and the other on to the groin. It measured over an inch in length and in depth. There was a slight papillary eruption over the face and extremities; the lymphatics were enlarged. Dr. Wyeth saw the patient on the 7th of August, at which time the eruption was well established. Some of the ulcers, especially upon the nose, looked like lupus; but the history of the case seemed to point clearly to a phagedenic pustular syphilide coming on soon after the constitutional infection. Dr. Wyeth held that the case illustrated the statements of Bumstead and Taylor that a pustular syphilitic eruption was apt to follow a phagedenic syphilitic ulcer, and that the violence of the disease was in many cases proportionate to that of the initial lesion.

Up to the time that he saw the patient, the latter had been taking blue mass in small quantities. Dr. Wyeth put him upon increasing doses of protoiodide of mercury, and, after three or four weeks, his condition began to improve. The strongest proof of the specific origin of the eruption was its response to antisyphilitic treatment. Dr. Wyeth remarked that he considered mercury a specific for syphilis, the same as quinine was a specific for malaria. Nevertheless, many patients who had syphilis doubtless got well without any treatment whatever, and, if it were a matter of choice, he would prefer syphilis to pneumonia or typhoid fever. Still, one could not say that the later manifestations of syphilis might not develop at any period during life.

Dr. LEVY spoke of the importance of building up the constitution of the patient.

The PRESIDENT remarked that he usually gave tonic medicines first, and, if necessary, began the administration of mercury later.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of September 17, 1884.

A Case of Frühjahrs-Catarrh.—Dr. HOWARD F. HANSELL read the following history: Michael Wood, aged twelve, applied at the Southwestern Hospital, in the early part of July, on account of inflammation of the eyes. His father, who accompanied him, stated that every spring, as soon as the cold weather had gone, Michael's eyes began to grow red. This statement is indefinite, but, as far as I can learn, is strictly true, for its advent is simultaneous with the onset of warm weather, whether it be in March or delayed until May. The eyes slowly grew worse during four weeks, when the acme was reached. The patient should be seen in the middle of the summer; then the disease is at its height, and the eyes present a remarkable appearance. However, the fall is not yet far enough advanced to have obliterated all the characteristic signs of his affection. These peculiarities are described by Arlt in his "*Klinische Darstellung des Auges*," and by Saemisch in von Graefe and Saemisch's "*Handbuch der Augenheilkunde*," in almost the same words. There is an elevation of the edge of the cornea, caused by infiltration of a gray, yellow, pulpy mass. On the limbus or margin are found small, gland-like, solid, light gray, or yellow, somewhat transparent bodies, which appear on the nasal or temporal side, or both together, and slowly encroach on the bulbar conjunctiva. As they grow along the edge, they advance on the transparent part of the cornea, and are sharply lined from it, while they imperceptibly fade into the conjunctiva. They are tough, immovable deposits, and do not yield to the probe. The conjunctiva in pronounced cases has lost its transparency, and its enlarged vessels run into the elevations on the cornea. The color of the conjunctiva differs from that of inflammation, as well as from the normal; it is steamy, dull, pale red, wanting the freshness and liveliness of acute catarrh. This is due to the light serous infiltration of the part.

This condition of the conjunctiva is called by German authors "*Frühjahrs-Catarrh*," and is without a name in English. The title is a bad one, because the affection is not a catarrh, neither does it exist only in the spring. It is a periodic or annual hypertrophy of the conjunctiva and the neighboring section of the cornea. An acute catarrh may be associated with it, as was in this case during part of July. This rapidly disappeared under treatment. The hypertrophy, however, resisted all treatment. For several weeks I kept the eyes under the influence of atropine, and three times each week I applied a crystal of sulphate of copper to the lids without the slightest benefit. Since August 1st the treatment has been stopped. The disease continues to appear regularly at the beginning of warm weather, reaches its maximum intensity in four weeks, and disappears after the first snow, leaving no trace. This is repeated for a period usually of four years, although it may run on many years longer.

Treatment has little or no effect; the only references which I have been able to find are the two mentioned above, although I have searched the works of Stelwag, Carter, Schweigger, Jacobson, and Soelberg Wells.

Dr. E. O. SHAKESPEARE had seen this affection a few times. It was one which he had supposed to be peculiar to the spring of the year, having in mind two cases that had so occurred, but he had seen one which appeared semi-annually. As to the pathology, he was at a loss to form an adequate understanding.

Dr. SAJORS would like to know if there was much pruritus.

Dr. HANSELL said that these cases occurred very rarely in this country. Dr. Harlan, to whom he had sent the case, in his many years of clinical experience at the Wills Hospital, had never seen a single instance of it. Neither had the speaker been able to find any reference to it among American writers. In answer to the question as to its connection with hay fever, I might say that this disease had a different history and pathology, and in the reported cases had been associated with no other affection. It bore a closer resemblance to pterygium than to any other eye disease.

Foreign Body in the Interior of the Left Eye, of Three Years' Duration, causing Sympathetic Ophthalmia of its Fellow; Removal of the Foreign Body; Full Recovery of the Right Eye; Marked Improvement of the Left Eye.—

Dr. M. LANDESBURG said:

I have the honor to exhibit to you, Mr. President, to-night, one of the most interesting cases I have ever had the good luck to meet with in my practice.

This gentleman, forty-one years of age, had the misfortune of being struck by a splinter of metal in his left eye, July 13, 1881, about six weeks after he had come to this country. Blindness set in within ten minutes after the accident. He applied on the same day at the Wills Eye Hospital, where he was advised to have the eye removed at once. Not quite relishing this prospect, he went to the Jefferson Medical College, where he was admitted for treatment after he had refused the enucleation, which was also at first proposed to him. There he remained for six weeks, during which time the incident inflammation passed off entirely. The globe was preserved, but vision was not restored. He enjoyed good health until March, 1882, when the first symptoms of sympathetic disorders began to develop in the right eye. Asthenopic troubles made their appearance, followed by sensitiveness to light and photopsies. The acuteness of vision gradually diminished as well for distant as near objects.

And now he began his wanderings from one oculist to the other; he hardly spared one, if I have to believe his testimony. Nothing was done for the benefit of the right eye, which changed from bad to worse. Enucleation of the left eyeball was pronounced by all authorities as the ultimate ratio by which the condition of "nervous irritation" in its fellow might possibly be checked.

When I saw the patient for the first time, September 5, 1883, I ascertained the following condition: No irritation whatever in either eye. Vision of the right eye was 10-20; with convex 40, 10-15. Pupil of normal shape, but of somewhat sluggish reaction; accommodation is impaired in consequence of paresis of the accommodative muscle. With naked eye patient reads Jaeger 13 at about fifteen inches distance; with the help of convex 10, Jaeger 3 at eight inches. Field of vision and tension are normal. There exists an eccentric positive scotoma, outside of the point of fixation. The subjective complaints are of photopsies and scintillations. Ophthalmoscopic examination reveals no morbid changes. Left eye counts fingers at two feet peripherically outward. The cornea shows a linear horizontal cicatrix on its lower third, running from the outer corneal margin toward the pupillary region. The lower half of the iris is disorganized and presents in its middle a funnel-shaped depression, and close to its temporal border a mound-like elevation. The pupillary margin of this segment of the iris is connected by three blackish filaments with the dense opaque whitish membrane, which stretches across the whole pupillary plane, filling up the latter to the greatest extent, even after the pupil had been dilated by a mydriatic.

The presence of the above-described "*depression and elevation*" in the lower half of the iris, which were situated just

opposite the corneal scar, aroused my suspicion that the foreign body might possibly lay imbedded in this region. An operation for the removal of the foreign body seemed to me to be a matter worth trying at first, by which nothing was risked and everything might be gained. The enucleation of the eyeball I regarded as the last expedient, to which I would resort if I should be baffled in my intentions.

I spoke with the patient to this effect, telling him that I must have full liberty to act according to my best judgment, and to be allowed to enucleate the eyeball if I should fail to extract the foreign body. He took time for deliberation and reflection until May 19, 1884, when he returned in the following condition. Meanwhile he had repeated and completed his circuit among the specialists. Vision of the right eye 10-30; with convex 60, 10-20; complete paralysis of the muscle of accommodation. With the naked eye he reads Jaeger 16 at eighteen inches distance; with the help of convex 10, Jaeger 5 at ten inches. The shape of the pupil is normal, its reaction sluggish. The visual field is somewhat limited in the upper sector, and its outer-upper quadrant is occupied to the greater extent by the eccentric positive scotoma. Patient sees all objects as through a veil, and is greatly annoyed by photopsies and scintillations, and by the perception of a bluish flame, which constantly occupies the center of the visual field. He complains, besides, of the most various abnormal sensations in and around the globe, of a feeling of pressure in the depth of the orbit against the eyeball, of pains in temples and forehead, of sensitiveness to light, etc. The ophthalmoscopic examination reveals venous hyperemia of the retina. Optic disk is pinkish red, of somewhat indistinct tints. The condition of the left eye has not changed.

I operated upon the left eye in the following manner: I made a section at the sclero-corneal border, just within the limits of the morbid changes in the iris, introduced Liebreich's iris-forceps, grasped the whole segment of the iris, which contained the "*depression and elevation*," drew it out and cut it off. No foreign body was found in the excised piece of iris. Now I again introduced a pair of forceps, caught the membrane, which covered the whole pupillary region, and managed to remove it entirely. On inspection, a small oblong piece of metal was found imbedded in the posterior surface of the lower end of the membrane. Considerable hemorrhage followed the operation, and a few drops of vitreous escaped from the wound. A compressive bandage was applied on both eyes.

No reaction whatever followed the operation, and the healing process took place most favorably. The bandage was removed on the third day. When I examined the patient on the eighth day, the condition was as follows: Vision of the right eye, 12-15; with convex 72, 12-12; Jaeger 12 is read at fourteen inches distance with the naked eye. Subjective complaints greatly abated. No photophobia and lachrymation. Scotoma somewhat more transparent. The left eye shows a very fine artificial pupil. The hemorrhage in the anterior chamber is only partly absorbed. Vitreous contains blood and dense floating opacities.

This remarkable improvement in the condition of the right eye had taken place without any other influences having been brought to bear upon it than the extraction of a foreign body. I abstained from all therapeutics during the eight days, and no more forcible proof of the sympathetic nature of the affection can be adduced than the spontaneous recovery after the cause of irritation had been removed.

An alterative and derivative treatment, which I now instituted, had the following effect: Vision of the right eye is at present 12-8. The pupil is of normal reaction, the accommodative paralysis has greatly improved. His punctum proximum is at fifteen inches, and he reads, with the help of convex 10,

the finest print (Jaeger 1) at six inches distance. The visual field is normal and the scotoma has contracted to an oblong rod of about two inches in length and of one eighth inch in diameter. This scotoma is transparent, and does not interfere with vision. All subjective complaints and perceptions have vanished, with the only exception of the bluish flame, which, however, but faintly and only occasionally appears in the visual field. Background of the eye is normal. Vision of the left eye is 1-16, and may possibly improve still more in the future. There still are large floating opacities and some bloody streaks in the vitreous. The background of the eye can only dimly be seen. There are morbid changes in the retina and choroid, due to inflammatory processes which had taken place in these parts.

You have, gentlemen, before you a case in which a foreign body had penetrated into the eyeball, causing traumatic cataract and consequent morbid changes in the uveal tract and retina. The lens is absorbed, and a thick, opaque membrane (secondary cataract) obstructs the whole pupillary region. The foreign body remains imbedded in the posterior surface of the lower end of this membrane for nine months, without doing any harm. Then the right eye begins to show symptoms of sympathetic trouble. Amblyopia and paralysis of the muscle of accommodation develop. And, while these morbid changes of the most serious character take place, no inflammation proper, no objective irritation, can be observed in either eye. The injurious influences, which have continued to work for two years, are checked at once by the removal of the foreign body. The secondary affected eye makes a marvelous recovery, which far surpassed all my hopes and expectations. Such a vision as 12-8 is only met with in very rare instances, and the primary injured eye, which was not considered worth while being preserved, improves to such a degree as to enable the patient, should he have the misfortune to lose his right eye, to find his way in the streets, to recognize faces, to distinguish features, and eventually to gain a living by peddling, etc., if need should be. This case may justly be called a triumph of conservative surgery.

Dr. SHAKESPEARE said this was a case of more than ordinary interest from many aspects, and Dr. Landesberg had rightly called it a triumph of conservative surgery. It was well known that a foreign body might remain in place many months or years before causing sympathetic irritation. The whole case, while an illustration of the benefits of conservative surgery, also showed the advisability of gaining the patient's consent to enucleation, if necessary, before the search was begun. These cases might, however, cause, in the minds of the laity and members of the general profession, erroneous impressions of the absence of danger from foreign bodies in the eye.

Dr. ROBERTS thought Dr. Landesberg deserved great credit for his acumen in supposing that he could remove the foreign body. He always warned patients, who came to him with lost vision from bodies in the posterior portion of the eyeball, of the danger of future sympathetic ophthalmitis, and advised them to have enucleation performed, unless they lived in the portions of the country where skilled ophthalmologists were found. This case would incline him to make exploratory procedures before enucleation.

Dr. W. S. STEWART asked the nature and size of the body.

Dr. LANDESBERG, in closing the discussion, said: I take exception to the practice of all those surgeons who resort, without further delay, to enucleation in instances of injury to the eyeball with loss of vision. In all cases in which there is no foreign body in the interior of the globe, we have to abstain from operative interference, and watch the eye with care. There is no danger in waiting. Sympathetic irritation is not likely to occur immediately after the injury. Enucleation itself is not so harmless as it is generally represented in text-books. It may

sometimes give rise to sympathetic irritation, and I would impress this fact upon the general practitioner. It is not indifferent to the patient whether his blind eye is removed or not. A blind eye looks, in the great majority of cases, better than an artificial one, and we have to give the patient the benefit, so long as it is compatible with the safety of the other eye. It is a matter of aesthetics. If a foreign body has penetrated the eyeball, the first indication is to remove it with an electro-magnet. If it can not be found, and there is traumatic cataract, I would at once remove the latter—the body may be imbedded in it. Should this removal fail, I advise enucleation at the same sitting. The foreign body extracted in this case was about 3 mm. long, and of metal.

The Cure of Crooked Noses by a New Method.—Dr.

JOHN B. ROBERTS read the following:

I present this patient to show the manner in which I treat the very disfiguring lateral deformity of the nose so often seen after falls or blows which have fractured the septum and cartilages. The method is, I believe, original. It is certainly attended with very little inconvenience to the patient, who, after recovering from the anæsthetic, can at once attend to his occupation without wearing any apparatus to call attention to the surgical procedure by which his crooked nose is being made straight and shapely. The usual advice given to patients with deformed noses, from nasal fracture sustained in childhood or later, is to undertake no surgical treatment, but to become reconciled to the disfigurement of feature as best they may. This is, I am sure, improper advice. The cosmetic objection to a crooked nose is cogent; and, moreover, obstruction of one nostril, from the displaced cartilages, is a frequent accompaniment of such lateral deviation of the tip of the nose.

This man sustained, ten years ago, a fall upon his face, from which he recovered with the end of the nose bent to the right, and with considerable obstruction of the left nostril. I operated on him day before yesterday. You see now a straight nose, and nothing to call attention to the operation except a small piece of black court-plaster a little to the right of the nasal bridge. Just within the right nostril close inspection reveals the head of a pin, situated on the side of the septum, near the columella. The method of operation, therefore, is certainly not objectionable on account of making the patient unpleasantly conspicuous during treatment. This evening I merely wish to show the man, and refer to my method of dealing with such cases, because at a later time I hope to bring the subject of curing nasal deformities before the society in a more formal and elaborate manner. Then I may have no patient undergoing straightening of the nose to illustrate the remarks.

Replacement of the deformed structures in this case was very simple. With a scalpel introduced through the left nostril, I perforated the cartilaginous septum at its upper and back part, and made a long incision through it in a direction downward and forward. This permitted me to push the whole cartilaginous portion of the nose to the left and overcome, to a great extent, the lateral deformity. To retain the parts in this position I introduced a steel pin about one and one fourth inch long into the right nostril, and passed it completely through the anterior and upper segment of the divided septum, near the columella. Having the movable portion of the septum thus transfixed, I was enabled, by carrying the head of the pin to the left, to move the anterior part of the nose to the left, and to retain it there by imbedding the point of the pin deeply in the immovable cartilaginous septum and mucous membrane at the back of the left naris. In other words, I incised the deformed cartilage, and pinned it in position very much as you would pin a flower in the button-hole of a coat. There still remained a little deflexion of the end of the nose to the right,

which seemed to be due to malposition of the lateral cartilage close to the right nasal bone. With a tenotome in the right nostril, I pared the cartilage loose, without perforating the skin, and pinned the parts over to the left by a second pin inserted from the cutaneous surface of the dorsum on the right of the median line. The point of this pin was fixed by having its point imbedded in the tissues of the left naris. It is the head of this second pin that is covered by the small square of court-plaster. The correction of the angular deformity of the septum removed most of the occlusion of the left nostril, which had greatly annoyed the patient.

I have thus given an idea of the method which has, I believe, great capability for relieving unsightly nasal deformities. The novelty consists merely in pinning the parts in position until cicatrization takes place. Endeavors have occasionally been made, as by Mr. Adams, Dr. Weir, and others, to hold deflected noses in position, after operation, by the use of clamps, rods attached to the forehead, adhesive plaster, plugs, and similar devices. All of these are objectionable, because so conspicuous and troublesome, and would probably be adopted only in instances of great deformity. The pin method, however, leaves no noticeable scar, is not troublesome to the patient, and is applicable, therefore, even to those slight deformities whose chief annoyance is an æsthetic and cosmetic one. I leave the pins in position for about two weeks.

A few years ago Dr. Mason, of Brooklyn, recommended the use of steel needles to hold the nasal bones in position, when, after recent comminuted fracture, it was difficult to keep the fragments sufficiently elevated. He transfixes the nose below the depressed fragments, and carries a piece of plaster or a rubber band across the external surface of the bridge from one end of the needle to the other. The needle acts as a girder to tie the base of the nasal arch and prevent its falling in. This is a different use of the pins or needles from that which I am describing, and for a different purpose.

I have pins of lengths varying from one inch to two and one fourth inches, and with flat heads, so that there will be little projection under the court-plaster to attract attention when the patient is in public. The heads are square, that the pins while imbedded may be, if necessary, readily rotated by the fingers.

When the deformity is in the osseous portion of the nasal bridge, section with small chisels is usually necessary. Discussion of this topic, however, would carry me beyond the limits of the present subject.

Free incisions are essential in obtaining good results in cases of nasal deformity such as was exhibited by this patient. The surgeon must not spare the knife and thereby spoil the nose. Secondary operations may sometimes be required to get the best results. If a simple incision did not allow proper adjustment, I should excise portions of the cartilage with the oval punch or the scalpel, or make multiple stellate incisions with the stellate punch, and so produce general flexibility of the cartilage.

Recurrence of deformity would, I think, be less likely to occur after free incision, pinning, and cicatrization, than after simple dilatation, with or without incision with the stellate punch.

Dr. JUIST had been so unfortunate as to operate in a few cases of divided septum, but had generally found that after two or three months the septum returned to its former position. He hoped Dr. Roberts would state whether in his cases it remained permanently straight.

Dr. ROBERTS said that, if free incisions were made, the deviation ought not to return. If, after operation, the parts were held in place two weeks, the chances were that they would remain in the new position as surely as after the original accident.

Dr. JURIST would not like Dr. Roberts to understand that he did not fracture the septum. He did so in all cases—using the stellate punch—and did not rely simply on a plug.

Notes on a Case of Poisoning from Mrs. Winslow's Soothing Syrup.—Dr. A. B. HUSSIN read the following:

With the object of adding my quota to the list of serious accidents resulting from the indiscriminate sale of secret medical preparations, I have gathered the notes of the following case:

Mrs. A. H. L. took her twenty-months-old boy to visit some friends, and, while there, they (all unknown to her) fed him some unpeeled apple and other indigestible material. Being colicky all that night and next morning, she was persuaded by a "friend" to purchase a two ounce phial of the nostrum sold as "Mrs. Winslow's Soothing Syrup," and of this gave him half-teaspoonful doses, as the directions called for, although she insists half of each quantity was spilled through his struggling.

He took, therefore, the first dose at four o'clock on Sunday afternoon (August 24th), and, there being no effect, another at eight; then dozing but not sleeping from this time till three next morning, the pain starting him again to whining, he was dosed at five; still crying on, three quarters of an hour later the final similar amount was administered. The mother soon became alarmed at the marked stupor which had now set in. He would touch none of the breakfast placed before him, Mrs. L. said; although sitting upright in his high-chair, his head hung listlessly, and he recognized nobody.

I saw him at 7.45 A. M., and found marked symptoms present of poisoning by some narcotic drug. The pupil was contracted down to the typical pin-head; stupor was unmistakable; respiration was very slow, gasping, and shallow, while at irregular intervals he would take two or three rapidly succeeding deep sighs; the pulse was rapid and small; the extremities were cold throughout the case. Taking all these symptoms into consideration, and the fact that the breath bore the peculiar odor of an opiate, I felt warranted in treating the case for one of poisoning by some preparation or derivative of that drug.

The stomach and bowels were emptied at once; frequent cold sponging was ordered, with wet cloths placed on the nape of the neck whenever great trouble existed in keeping him awake. Tincture of belladonna was given hourly with water. The parents were directed to keep him awake by all means.

By noon he would begin to lift the eyelids a little, but relapsed into a sort of doze by 2 P. M. Despite all their efforts, he fell once more into a stupor by six. Calling about this time, I insisted on the mechanical exercises being continued, feeling encouraged by the somewhat improved breathing, and I succeeded a little while later in arousing him. As the pupil had now slowly begun to dilate, the medicine was ordered to be given every half-hour, or twice as often as before. By eleven he began to lighten up, and, on calling half an hour later, I found him languidly trying to push his ball around the table upon which he sat; the pupils were widely dilated, and respiration was free. He was allowed to sleep, with slight interruptions, from midnight until 6 A. M., after which he showed his great thirst by frequent demands for ice-water. Incoordination of the voluntary muscles now became noticeable, and continued until next morning. A typical belladonna rash was now likewise beautifully shown, also to disappear in time. He slept for two hours about noon, being exceedingly irritable afterward, but, excepting the use of a tonic, required no other treatment.

As stated in the beginning of the notes, this case is merely placed on record to help expose an existing evil, believing that continuous agitation will finally induce the intelligent public to demand the regulation of the sale of patent medicines, a fact concerning which there never was any doubt in the profession.

A fatal result would inevitably have occurred here had no treatment been instituted, and I feel convinced that many such cases happen in our midst which should be reported; incidentally conversing with both Dr. Schoales and Dr. Blackwood, I heard of such occurring in their respective practices, and should be glad to hear more fully of them from those gentlemen.

The case is the more pertinent at this time when any fakir or shop-keeper may legally retail unlabeled poisons in the guise of patent medicines, while one of our inconsistent laws is now being so interpreted as to inform the patient that, in very many cases, his doctor has prescribed him medicine containing poison.

Dr. JOSEPH D. SCHOALES remembered a similar case, in a child sixteen months old, with which he sat up a whole night. It recovered under a treatment for opium narcosis. In another child, five months old, the symptoms resembled those produced by a teaspoonful of laudanum. Fifteen drops of the syrup had been given. Neither case resulted in death.

Dr. HUSSIN recalled a case in which trouble and annoyance had arisen from a physician's prescription being marked "poison" by the druggist. This occurred after the recent fiasco in which such notice was ordered in each case by the coroner's deputy, an interpretation of the State poison law since reversed by the court. An explanation was necessary before the patient consented to take the medicine and to continue with the physician.

Miscellany.

THERAPEUTICAL NOTES.

Hypodermic Injections of Strychnine in the Treatment of Paralysis.—Dr. Galicier, of Versailles ("Moniteur de thérapeutique"; "Bill. gén. de thérapeutique"), states that strychnine injected hypodermically in cases of paralysis produces a local as well as a general therapeutic effect. The local effect is manifested more or less quickly according as the power of the muscle is completely abolished or only more or less impaired; in from one to five minutes in the latter case, and in from five to twenty minutes in the former. Sometimes, but rarely, the action is delayed until the second or third injection. In the latter case, the power of motion acquired does not at first last from one day to another, but a series of injections is necessary to fix it. The general therapeutic effect is shown progressively after a series of injections, and there is nothing special about it.

From a therapeutic point of view, then, strychnine by hypodermic injection acts like electricity in paralysis—an analogy long since known in general terms: it isolates muscular action and decomposes the motion—in a word, after the manner of electricity, it is an analytical agent in its local action, and a synthetic agent in its general action. These two effects combined act in concert in the cure of paralysis. Like electricity, strychnine encounters resistance on the part of certain limbs, and these are the same in the two instances.

The Treatment of Cold Abscesses by Injections of an Ethereal Solution of Iodoform.—Verneuil's method, as described by the "Revue de thérap. méd.-chir.," consists in injecting into the cavity of the abscess, previously emptied by aspiration, a one-to-twenty solution of iodoform in ether. The quantity of fluid injected may reach three hundred grammes without causing any symptoms of poisoning. This method is said to give very satisfactory results, and to be quite free from danger; the injections can be repeated if necessary.—*Brit. Med. Jour.*

The Action of Salicylic Acid on the Respiration in Typhoid Patients.—The Paris correspondent of the "British Medical Journal" writes to that journal that M. Bochefontaine concludes from experiments that salicylic acid has a favorable influence on the respiration in typhoid patients, restoring the normal amplitude and rhythm of the movements, and thus allowing hæmatisis to regain its lost activity. In healthy animals, submitted to the influence of the drug, the inspira-

tions are prolonged at the same time that the temperature is reduced, and the same correlation holds good in typhoid patients—after doses of from five to six grammes, their temperature falls rapidly, and at the same time the respirations become normal. This action of the salicylic acid can not be attributed to a modification of the blood. Experiments have demonstrated that the quantity of the drug which enters the economy after being absorbed by the stomach does not have this effect. The heart is not affected either by the acid or by salicylate of sodium. Experiments made on animals with poisonous doses prove that this organ preserves its movements; even when the muscular fiber and the ganglia cease to perform their functions, *rigor cadaveris* sets in. It has also been demonstrated that non-toxic doses act on the nerve-centers. M. Bochefontaine took three grammes of the acid daily, one half at noon, and the other half at night. Each time that he repeated the dose he was unable to walk, from a feeling of fatigue. If he sat down, this sensation disappeared, and his condition was perfectly normal. He concludes that, in non-toxic doses, salicylic acid acts, in man as in animals, on the medulla oblongata, and that its regulating effect on the respiration in typhoid patients is due to its action on the respiratory center of the medulla.

The Buffalo Lithia Water.—Dr. M. H. Houston, of whom the editor of the "Virginia Medical Monthly" says that he is well known to the profession in that part of the country for his valuable contributions to medical literature, and for a ripe experience and careful habit of recording facts which add weight to any statement coming from him, writes to our esteemed contemporary as follows:

"The remarkable medicinal properties of these waters should be more generally known to the members of the profession in every part of the country.

"These springs belong to that rare class of mineral waters which, without any very sensible qualities to distinguish them from ordinary water, yet exert a quiet and mysterious influence over the animal economy, which, in many cases, is as wonderful as it is gratifying. There is nothing in the analysis of the water which exists in quantity sufficient to account for its peculiar action. The remark applies more forcibly to this class than to most mineral-waters. It may be said, however, of all mineral-waters, that analysis can never reveal the combinations upon which their efficacy depend. In fact, the very process of analysis may break up combinations, formed in the laboratory of nature, which the best skill of the chemist can never detect, and which may impart to them their most valuable properties.

"Having had an opportunity of watching very closely the action of the lithia water, in numerous cases which have fallen under my observation, I am prepared to impute to it one quality at least, to which, it strikes me, sufficient attention has not been heretofore directed. I allude especially to its power as a gentle excitant to the nervous system, and as a *powerful and permanent nerve-tonic*. To this peculiar property I am disposed to attribute much of its efficacy in the relief of many chronic diseases. Other mineral-waters, with exhilarating properties, are sparkling in their appearance, and their exciting qualities are due to the gases which are disengaged, and which are, consequently, evanescent in their effect. The lithia water is without such impregnation of gases, and its effects are much more permanent.

"In a case under my immediate observation, in which there was congestion of the mucous membrane of the fauces, œsophagus, and probably of the stomach, accompanied by extensive and very painful hyperæsthesia of the whole skin, its effects were very remarkable. A full goblet of the water of Spring No. 2, taken about eleven o'clock, was followed, in a few minutes, by a sensation described as a *lightening up of the whole system*, as though a load had been removed from it, and an almost entire cessation of numerous neuralgic pains in different parts of the body. There was none of that exhilaration of the brain caused by alcohol in any of its preparations, or by any other mineral water that had ever been tried. The result was manifested too soon to be accounted for on any other supposition than that it acted directly on the nerve-filaments of the stomach, and through them, by reflex action, on every other part of the system.

"It may be remarked here that hyperæsthesia generally may result from two opposite conditions of the nerve-centers: one of active, and the other of passive congestion. Active congestion or inflammation is

attended with exaltation of nervous sensibility, while passive congestion is the result of depressed nervous energy, with *perverted* sensibility. When not the result of organic disease, a large majority of the disorders of the digestive organs are caused or accompanied by the latter condition; and it is to its immediate effects upon this perverted sensibility that I am disposed to attribute, to a great extent, the salutary effects of the water. Its direct impression on the nerves of the stomach is the first important link in the chain which connects it with the gradual improvement produced in the other organs of the body—and this improvement is rendered permanent by its nerve-tonic power. This peculiar property of the water would seem to indicate it as peculiarly applicable to those forms of paralysis caused by pressure upon the cord, from passive congestion or serous effusion. In this class of cases all remedies, including galvanism, are, more or less, necessarily tentative, but I have no hesitation in advising its use, especially in cases of long standing.

"Add to this nerve power its impregnation with alkaline salts, and you have a combination especially adapted to the relief of that large class of disorders of the digestive organs, accompanied with passive congestion of the mucous membrane, with perverted sensibility; or, as they were graphically described, about fifty years ago, by the celebrated Dr. James Johnson, under the head of 'Morbid Sensibility of the Stomach and Bowels.'

"The impression made upon the nerve-filaments is communicated, by contiguity, to the blood-vessels in their immediate neighborhood, and the organic contractility thus acquired relieves them gradually of their accumulated contents; while, by reflex action, the same effect is produced, more gradually, on the mucous membrane in every part of the body; the appetite is improved, and with it the power of digesting the contents of the stomach. Its direct action on the liver is probably very limited. The functional disorders of this much slandered organ are due, in a large majority of cases, to irritation and inflammation of the duodenal mucous membrane, conveyed by direct sympathy, through the gall-ducts, to the body of the organ. The cause being removed, the liver returns gradually to the performance of its proper functions, and adds its healthy products to the completion of digestion.

"Its effects in improving and restoring the organic sensibility of the entire intestinal track were strikingly illustrated in one of the cases under my immediate observation, in which there was almost entire paralysis of the rectum. The rectum itself was distended into a sac, in which fecal accumulations took place to an extent that rendered it necessary to use mechanical means for their removal. Under a continuous use of the water, the sensibility was restored to a considerable extent; tonic contraction of the distended bowel took place, and its contents were expelled, with very slight assistance, from the use of simple water. Indeed, as far as any cathartic effects are concerned, they are due more to this restoration of organic sensibility along the whole track of the intestinal canal than to any drastic effect upon the blood-vessels.

"As an alterative and diuretic, its composition would indicate it as peculiarly appropriate. By reflex action it operates, in the same manner, on the irritated mucous membrane of the bladder, though more slowly than it does when applied directly to the mucous membrane of the stomach and intestines. A single case brought to my attention will serve to illustrate this principle. A gentleman, far advanced in years, labored under an irritation and inflammation of the neck of the bladder so extreme as to render it necessary for him to make efforts to relieve it from twelve to twenty times during the night. Under the use of the water the relief was so complete as to render it necessary for him to rise only once, and often not at all, during the night. As far as known, the relief thus afforded has been permanent.

"The foregoing remarks on the *modus operandi* of the water are derived mainly from observations made with the use of the bottled water from Spring No. 2. It can scarcely be doubted that they will apply with more force to the use of the water at the fountain-head.

"Spring No. 3, if it contains the same nerve-tonic as Spring No. 2, has also an increased quantity of iron, which would constitute it a valuable blood, as well as nerve tonic, in those numerous anæmic conditions usually met with in female diseases.

"It is not to be expected that in organic disease of any kind, and especially in those of a malignant character, a cure can be effected;

but it may be safely said that in many, even of such cases, it will be found a most valuable palliative.

"What has already been said will designate, to every intelligent physician, its useful applicability to a variety of other affections which need not now be enumerated. In this connection it will be proper to enter a caution against the too free use of the water under any circumstances. Being highly medicinal, it should, like all other important medicines, be administered, as far as practicable, under the advice of some judicious physician, who, from observation, has become familiar with its properties. If taken too freely, like all water, it will produce some sense of oppression of the stomach, and, moreover, a sense of constriction about the head, which is neither comfortable nor desirable. From all that has been said, I must conclude that, as a medicinal agent, this water has properties which render it quite equal, if not superior, to any mineral-water of which I have any knowledge."

A Classification of Urethral Applications is given by M. Mallez ("Rev. de théráp.," "Rev. méd.," "Gaz. hebdomadaire des sciences médicales de Montpellier") as follows:

Irritant injections.	Caustics.	Nitrate of silver.
		Bichloride of mercury.
		Caustic potash.
		Iodine.
Non-irritant injections.	Astringents.	Iodide of potassium.
		Protiodide of iron.
		Acetate of lead.
		Sulphates.
Antiseptic injections.	Detersives.	Lactate of zinc.
		Tannin.
		Catechu.
		Pure water.
	Protectives, or absorbents.	Red wine.
		Aromatic wine.
		Alcohol.
		Distilled water of cubebs.
	Anodynes.	Distilled water of copaiba.
		Distilled water of eucalyptus.
		Starch.
		Subnitrate of bismuth.
	Irritants.	Carbonate of lime.
		Various emollient decoctions.
		Opium, laudanum.
		Belladonna.
	Detersives.	Phenic acid.
		Protocloride of tin.
		Carbolized water.
		Chlorine or chlorides in water.
	Pure antiseptics.	Tar-water.
		Permanganate of potassium.
		Borax.
		Sulphite of sodium.
		Sulphite of silver.

Sanitation and the Rag Trade.—The limitations put upon the importation of rags, for the purpose of protecting the country against the introduction of infectious diseases, having been taken by the importers as an unnecessary hardship imposed upon them, the Washington correspondent of the "New York Herald" has been at some pains to get at the real position taken by the Government in the matter, and he reports that Surgeon-General Hamilton, of the Marine-Hospital Service, spoke to him as follows:

"In regard to the opinion of those able sanitarians, the rag importers, on the contagion or non-contagion of their wares, I am willing to admit the entire disinterestedness of their opinion on that subject, and also to admit their acknowledged ability as sanitary experts. I, however, must dissent from the opinion of even so useful a body in their statement that rags are all thoroughly disinfected either before or after shipment. The contrary is the fact.

"So far as the alleged good health of persons handling filthy rags is concerned, it must be placed on a par with the alleged good health of the workmen in the Paris sewers, who are also said to be quite healthy.

I do not believe, however, that the advocates of racial longevity would recommend a residence in the sewers or the handling of old rags for the purpose of prolonging life.

"Seriously, though, there is such a thing as the securing of immunity from certain diseases, known to be infectious, by constant exposure. Such immunity is also secured from the operation of certain poisons.

"So far as the burden of proof whether a given cargo comes from an infected district or not is concerned, in my judgment that burden should not be thrown upon the Government, but upon the importer. It is not sufficient that the rags shall have been shipped from a healthy port. It must be known from what sources they were originally gathered.

"The statement is made in the 'Herald' interview, to which you call my attention, that the public is misled as to the disinfection of rags previous to their shipment. That has been done in but a single instance, so far as I am aware, and that is the instance cited in the official memorandum. This Government is not alone in its regulations concerning the importation of rags, for importations are prohibited in Russia, Germany, Canada, Belgium, Italy, and Spain, and in England from infected localities.

"The suggestion has been made that the manufacturers are simply putting up their prices of paper on a pretext that there were already large stocks of paper on hand when the prohibition order was issued, and that paper which was not made from rags had been increased in price at the recent meeting of manufacturers. This office, however, is entirely uninfluenced by any such considerations. The question of a central disinfection warehouse in this country is one that may be acted on at the next Congress, at least the question will be distinctly submitted to them, and the present agitation can only result in the better security to the public health, either by disinfection of the suspected cargoes abroad or at home. The experiment of the Seymour Company proved that the expense of disinfection abroad was not an insurmountable one. In point of fact, the operation of boiling and drying the rags, which was adopted, might be considered one of the preliminary processes of the manufacture of paper, for the rags were thoroughly cleaned and freed from dirt at a comparatively trifling expense."

Melanuria.—Among some of the most interesting phenomena of physiological chemistry are the conditions of the urine as regards its colored constituents. As is well known, the pigments of urine are not all visible when that fluid is first passed—e. g., the presence of indican requires chemical manipulation for its detection. Zeller has recently observed a rare case of melanuria in a man aged forty-three, who was the subject of multiple melanotic sarcomata of the skin, and who died, six weeks after he was admitted to the hospital, of cerebral complications. The urine was of a brownish-yellow color, absolutely clear, of a density of 1020–1030, free from sugar or albumin. Chemical analysis showed a slight increase in the amount of sulphuric acid discharged; phenol and indican were of normal proportions, but the quantity of hydrobilirubin was largely augmented. There existed a constant relation between the black coloring matter and the bilirubin in the sense that when the urine was light-colored the more urobilin it contained, and the less melanin it had; the darker the urine the more melanin it yielded, and the less urobilin. Bromine-water gave an abundant precipitate, yellowish and amorphous, but, on resting, this changed spontaneously to black. The test with bromine proved to be more sensitive than that obtained with nitric acid or chromate of potash. The precipitate of bromomelanin appeared in the dry state as a brilliant black solid which became a brown powder when triturated. The bromine-reaction distinguishes melanin from urobilin, which gives with bromine water a yellow precipitate, not, however, passing into black when left to stand; so that normal and febrile urines do not give the black precipitate when treated with bromine-water. Zeller believes that the urinary pigments proceed from two sources, the one being the coloring matter of the bile or blood, and the other aromatic substances developed in the intestine during the process of digestion of albuminoids. It is probable from his observations that melanin is derived from the latter source, though the want of further investigation is admitted.—*Lancet*.

Lectures and Addresses.

OBSERVATIONS

ADDRESSED TO THE STUDENTS OF
BELLEVUE HOSPITAL MEDICAL COLLEGE

AND THE

MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK,*

THURSDAY, SEPTEMBER 25, 1884,

By W. S. PLAYFAIR, M. D., F. R. C. P.,

PROFESSOR OF OBSTETRIC MEDICINE IN KING'S COLLEGE, LONDON; LATE PRESIDENT OF THE OBSTETRICAL SOCIETY OF LONDON, ETC.

GENTLEMEN: My friend, Professor Lusk, has asked me to address a few words to you, and I feel too much indebted to him and to the many other kind friends who have given me so cordial a welcome on this my first visit to your great country, to hesitate a moment in complying with the suggestion he has made to me. At the same time, you must permit me to say that the last idea I had in my mind, in my visit to the United States, was that of appearing in any sense as a teacher. My object, if I had one beyond that of taking my annual vacation, was rather that of making myself again, in a degree, a student. I was desirous of seeing and studying your many valuable institutions, and of learning some of the lessons which a country so rapidly progressive as this is well capable of teaching to a traveler from the Motherland. In this I have certainly been amply successful. I feel that it is quite impossible for an Englishman to travel in the United States without acquiring knowledge which certainly ought, if properly assimilated, to be of much value to him. Professor Lusk, however, obviously did not ask me to address you with the view of eliciting my general impressions of American travel, so I shall say no more on this topic, but rather occupy the brief time I have at my disposal with some general remarks on the department of practice in which we are specially interested—viz., obstetrics and gynecology. I regret, however, that I had not the remotest conception that I should have the honor of addressing this large and important meeting which I see before me. Had it occurred to me that such an assemblage was possible, I should have endeavored to prepare myself more fitly for the occasion by getting ready an address on some special topic, which might have been, perhaps, more worthy of such an audience; but, not having had the opportunity of doing so, I can only crave your indulgence for the few scattered observations I can now make.

I have always been struck, in my general studies, with the fact that obstetrics and gynecology seem to be cultivated, on the whole, with more energy in your country than these subjects are with us, at any rate of late years. It is true, I think, that the first great start in what I believe to be one of the most progressive branches of medicine was due to the energy of my late honored master, Sir James Simpson, who, by his numerous researches and papers—per-

haps even more by his indomitable "vis viva," which one must have known to thoroughly appreciate—gave an impulse to the study of the subject which is felt to the present day. If any of you have the curiosity to look back to any of our standard works on gynecology antecedent to his time—say, for example, to the treatise of the late Sir Charles Mansfield Clark, who, some forty years ago, was *facile princeps* the leading gynecologist in England—you will readily understand how much the subject has advanced since that comparatively recent date, for you will not find in it any mention of such topics as the speculum, the uterine sound, flexures, or hæmatocele—so that what is now the very alphabet of gynecology was then unknown.

Since that time we have had some great advances in our country of which we have just reason to be proud—such, for instance, as the familiarization of the profession with ovariectomy and other branches of abdominal surgery in consequence of the labors of Spencer Wells and others, although in this connection we must not forget that the operation had long since been performed by your own Ephraim McDowell, of Kentucky, albeit he was not successful in popularizing it as a regular and every-day resource. Since then, however, although much attention is now paid to these subjects in Great Britain, and although we have many able practitioners who devote themselves zealously to its advancement, I can not but feel that it does not receive with us the attention which its great importance merits. Of course, there are many of my brethren, especially those whose professional pursuits are in other directions, who would not agree with me in this statement; if, however, you consider what an immense amount of the ordinary every-day work of the practitioner is in connection with midwifery and the diseases of women, how largely the health and happiness of whole families depend on an intimate knowledge of these subjects on the part of the medical attendant, you will probably agree with me that it is difficult to exaggerate their importance. Now, one of the reasons why, in Great Britain, those who are interested in these branches have good grounds for complaint, is one that I have always been preaching about, in season and out of season, on the other side of the Atlantic, and that is the absurdly inadequate time that is devoted to the teaching of obstetrics in our medical curricula. In every one of our metropolitan schools the course of midwifery is for three months only, and that is supposed to include teaching in gynecology and the diseases of children also, while the cognate subjects of medicine, surgery, and the like, have full courses of six months, besides abundant opportunities of clinical instruction by lectures and otherwise, which are denied to obstetric teachers. All this is the result of the survival of old prejudices, and undue dislike to what is supposed to be new and advanced, which is perhaps inevitable in an old country such as ours. Against such absurdities a constant battle has to be fought, and it is to be feared not always a very successful one, although, doubtless, much ground has been gained. In the mean time, however, there is a risk of the country being flooded with practitioners who leave their schools profoundly ignorant of departments of practice which but a

* From manuscript kindly prepared by Professor Playfair.

short experience of every-day work proves to them to be of vital moment, and which they subsequently have to acquire at the cost of much labor to themselves, if not of precious lives which have been intrusted to their care. In this respect you are, so far as I have had opportunities of seeing, distinctly in advance of us. The same amount of time, the same amount of teaching, is given to this as to other topics, so that if any of you gentlemen should chance to leave your school in comparative ignorance, the fault may possibly justly lie with you, and not with your teachers.

Then another great drawback we gynæcologists have to deal with in England is also an antiquated survival which hampers many of us sadly, and that is the old-fashioned distinction which we have between physicians and surgeons, and the idea that it is beneath the dignity of the former to handle a knife, or resort to any sort of operative procedure whatever. Most of our London hospitals are very ancient institutions. Many of them were in active operation before Christopher Columbus was born or America heard of, and their staff and organization to this day remain very much as they were at the time of their foundation. In bygone days, of course, midwifery was entirely practiced by ignorant women, and gynæcology was unknown. So it happened that the staff was composed of physicians and surgeons only, the obstetric physician coming in afterward as a sort of interloper, who was "neither fish, fowl, nor good red herring," and who to this day in some of our leading hospitals is not recognized as being on a footing of perfect equality with his colleagues. When the advancement of science rendered it necessary for him to perform surgical operations, the surgeon stepped in and said: "No, this gentleman is a physician; he must not operate." And so it chanced that at this moment there are only two large hospitals in London, one of them being happily my own, in which the obstetric physician is allowed to perform ovariectomy, perineorrhaphy, or any other surgical procedure. Now, I ask any reasonable man, How is it possible that gynæcology can make proper progress under absurd restrictions such as these? Gynæcology is as much surgical as medical, probably a great deal more so; and the modern gynæcologist who may not handle a knife is very much like a modern soldier who is prohibited from using gunpowder. Here, again, you have decidedly the advantage of us. You have no such old-world prejudices to deal with, and your physicians may be surgeons, or your surgeons may be physicians, just as much or as little as their individual tastes may prompt them to be. Hence it comes, to some extent, I think, that your lines are cast in some ways in more pleasant places.

When I reflect on what American gynæcologists have done, it is impossible not to be obliged to congratulate you on your good position. To Marion Sims we owe it that vesicovaginal fistulæ no longer cause life-long misery to those so unhappy as to suffer from them; to Emmet we owe the introduction of trachelorrhaphy and the recognition of laceration of the cervix as a common lesion and a fruitful source of uterine disease—a recognition as yet to a great extent limited to this country, since, when I introduced the topic to the Obstetrical Society of London, I failed to obtain for it anything like the attention its importance merits; while

to Battey, of Georgia, we owe the removal of the uterine appendages in certain cases of long-standing disease. I could point to other indications of the active interest taken in these subjects in America, notably to your valuable monthly "Journal of Obstetrics," full as it is of important matter, and to your "Gynæcological Transactions," while in London, with sorrow I say it, the one little obstetrical journal we had died, after a brief and troubled existence, from inanition.

Gentlemen, it struck me, when called on to address you, that it might interest you to learn something of our difficulties in England, and to know how we are interested in the progress of obstetrics—have to fight against certain discouragements. Perhaps, or at least let us lay the flattering unction to our souls, our record under the circumstances is not altogether so bad as might have been anticipated. I have alluded specially to three great modern improvements emanating from American gynæcologists. The first of these is now a matter of history. Marion Sims has unhappily passed from among us, and this portion of his work, and his name in connection with it, will be remembered and honored so long as surgery exists. The two others are still fruitful subjects of discussion, and there is some similarity in their present status from which, I think, useful lessons may be derived. The lesson I would venture to teach from these is that undue enthusiasm, over-riding of a favorite hobby, always harms what may be a good cause, and so really retards, instead of promotes, true progress. Some of my professional brethren in America, I have reason to know, feel somewhat aggrieved, and I think not without reason, that the work done on this side of the Atlantic, with regard to traumatic lesions of the cervix, their effects, and their cure by operation, has never been fairly taken up and studied in England. The facts I believe to be undoubted, and not to our credit; the reason, I think, is not far to seek. No one can accuse me of this fault, since I believe I was the first to perform trachelorrhaphy in Europe. I have long since recognized its value, and brought it before the profession, and I have the reputation at home of being a thick-and-thin supporter of the operation; so I will assume the position of the "d—d good-natured friend" and point out to you that the prejudice against the operation may, I think, be traced to the undue enthusiasm that it excited here, to the suspicion that it was resorted to in many cases unnecessarily—in fact, to riding the hobby too hard. Things are certainly righting themselves here. Surgeons are everywhere beginning to recognize the fact that all lacerations of the cervix do not require to be operated on, and I do not doubt that before long the value of this operation will be properly estimated on both sides of the Atlantic.

The removal of the uterine appendages stands, just now, on much the same platform, although, curiously enough, the hurtful enthusiasm of some of its advocates is of English, not of American growth. This topic has lately been the subject of an address delivered at Montreal by my countryman, Mr. Lawson Tait, which has been published in your medical press, and has been much commented on. With regard to Mr. Tait's purely professional views I have no criticism to make

at all. On the contrary, I believe him to be doing a considerable work, to be pointing out a real advance, and I am, in the main, a believer in it. I have only to say, with reference to it, what I have already said to him elsewhere, that I think his work is and has been retarded, as I have pointed out that trachelorrhaphy has been here, by injudiciously hard riding of a favorite hobby. But, as the first Englishman who has addressed an American audience since that address was delivered, I do feel impelled to protest against what I can not but think was the unhappy spirit that pervaded it, especially the invective on names honored all over our country. In England for any one to say a word in defense of Sir Spencer Wells's position would be absurd; when, however, it is broadly insinuated in America that his title and his honors have been gained on false pretenses, it may be well to assure you that probably Mr. Tait stands alone among Englishmen in holding that view. That Sir Spencer Wells's record may have been surpassed of late is probable and natural as science advances; if it be so, it does not deteriorate one whit from his merits as a pioneer. Gentlemen, the world is never wrong in its estimate of its great men, and if nine hundred and ninety-nine men tell you that Sir Spencer Wells is a great man and an eminent surgeon, and one man tells you he isn't, "you bet"—if I may be permitted to use a local phrase—that the nine hundred and ninety-nine are right and the one is wrong. I can hope for no worse condemnation of my countryman's address on this point than that it should be as severely animadverted on at home as I have heard it here by some of your highest authorities.

And now, gentlemen, I must bring these disjointed remarks to a close. If I have had to conclude that you are in some respects better off than your British relatives, you will, I am sure, not suppose that I intended to please you with honeyed words. In case you should, I may conclude with the reminder that, if you have such facilities in the study of these important topics, if you have the example of so many of your distinguished gynecologists to follow, these advantages carry with them corresponding responsibilities, and of these, I trust, you will never be unmindful.

Original Communications.

ON THE PARASITIC DOCTRINE OF EPIDEMIC CHOLERA.*

By AUSTIN FLINT, M. D.

MR. PRESIDENT AND FELLOWS OF THE NEW YORK COUNTY MEDICAL ASSOCIATION: What is the present status, as regards our actual knowledge, of the parasitic doctrine of epidemic cholera? Have the researches of Robert Koch and others shown this disease to be dependent on the presence of a particular microbe or micro-organism? In other words, has epidemic cholera been proved to be a parasitic disease?

* Read at a stated meeting of the New York County Medical Association, October 20, 1884.

In order to discuss and decide upon these questions, it is by no means essential that we shall have practically verified the microscopical examinations on which rests the evidence of the parasitic doctrine. In courts of law, the judges, advocates, and juries are not themselves observers of facts involved in cases on trial. They deal with facts as established by testimony. So it must be with scientific facts. They are to be canvassed, and either accepted or rejected on the statements of competent witnesses. Were it otherwise, very few of those interested in the developments of science would be qualified to judge of their validity. With regard to the micro-organism which, as it is claimed, is the essential cause of epidemic cholera, an opportunity for personal investigation is not, and, as we may hope, will not, be offered in our own country. Were the opportunity to be offered, how few have the time and patience, added to the knowledge and skill to be acquired only by proper training and practice, to conduct microscopical observations! When in London during the past summer, I visited the Biological Department of the Health Exhibition at Kensington Gardens, and I saw there a specimen of the so-called cholera bacillus. It had been prepared by Koch himself. The demonstration was interesting, but it would be absurd to claim therefrom any advantage in judging of the merits of the doctrine which assumes that this organism is the essential cause of epidemic cholera.

As a preliminary inquiry, let me ask, What is the status of the parasitic doctrine irrespective of any facts relating to the discovery of micro-organisms in cholera, or even in any other disease? It is logically certain that the diseases now classed as infectious diseases involve each a distinct specific causative agent of some kind. That this agent is a living organism is the most rational supposition. The so-called "germ-theory" offers the only possible explanation, with our present knowledge, of clinical facts pertaining to the history of infectious diseases—to wit, the production within the body of the different contagia, and of certain morbid miasms outside of the body, the periods of incubation and the definite duration of these periods, the self-limitation of these diseases, and the different laws which they respectively observe as to the length of their career. Many years ago the late Registrar-General of Great Britain, Dr. William Farr, classified the infectious diseases under the name "zymotic," and this term was generally adopted in England and in our country. Now, *zymosis* signifies fermentation, and the appropriateness of the name consisted in the reasonableness of the doctrine that the so-called zymotic diseases involve a morbid agent of the nature of a ferment. Since the introduction of that term into medical nomenclature, thanks to the genius of Pasteur, fermentation has been shown to be due to the presence of micro-organisms. The different ferments are different bacteria. At the present time the term zymotic implies the germ-theory as applied to the diseases thus designated.

It is therefore noteworthy that the discovery of micro-organisms as causes of infectious diseases, so far from being in opposition to previous opinions, is, in reality, a confirmation of the prevailing views of the aetiology of these diseases. And it is a fact, which in this country should not

be forgotten, that one of our eminent teachers and writers, the late Professor J. K. Mitchell, anticipated the confirmation of the germ-theory in a most ingenious and able monograph, entitled the "Cryptogamic Origin of Diseases," published nearly half a century ago. Mitchell's work, at the time of its publication, was regarded as more fanciful than rational; but the developments of the microscope within the last few years have shown that the author was gifted with a remarkable foresight.

Let me premise another consideration. At the present time there is no room for doubt as to the dependence of certain infectious diseases on specific micro-organisms. It is enough for my present purpose to assume this fact as applied to but a single disease, although the fact in reality holds true with regard to several diseases. Now, if it be demonstrated that any one of the infectious diseases is caused by a specific parasitic organism, is it not a rational inference that the remainder of these diseases have a similar causation? Reasoning by analogy, as it seems to me, we are warranted in concluding, logically, that all the infectious diseases are parasitic, and it remains only to demonstrate the particular parasite which stands in a causative relation to each of these diseases.

I come now to the inquiry as to the knowledge acquired within the past few months, chiefly through the researches of Koch, of the parasitic doctrine of epidemic cholera.

As is well known, shortly after the outbreak of cholera in Egypt in 1883, a scientific commission, with Koch at its head, was sent to that country by the German Government to investigate the disease. Subsequently the commission visited Calcutta for the same object, and more recently Koch has studied the disease at Toulon, in France. The different stages of progress made in the investigations were communicated to the German Government in a series of reports, of which a summary is contained in an address by Koch at a meeting of conference held in Berlin, July 26th. At this meeting several eminent physicians of Germany were present, Virchow being the presiding officer.

In view of the symptomatology of cholera, the investigations of the commission were especially directed to the alimentary canal. Many varieties of bacteria were here found, but a particular bacterium was observed which was distinguished from the others by its form and its situation. It was apparently rod-like, and, therefore, was considered to be a bacillus. A distinctive feature was a curve, which led to the comparison to a comma, and hence the name "comma bacillus," by which it is now commonly designated. From the corkscrew shape which some specimens presented, however, it is doubted by Koch whether the organism really belongs among the bacilli. Taking into account other circumstances in connection with the shape, he is disposed to regard it as a spirillum. This micro-organism was observed in more or less abundance, among other bacteria, in the contents of the intestine, and also within the tubular glands, between the epithelium and the basement membrane of the intestinal walls, and in a still deeper situation. The investigations in relation to this so-called comma bacillus, pursued in Egypt, in Calcutta, and in Toulon,

resulted in the conclusion that it is the essential cause of cholera.

That the comma bacillus is a veritable organism is not doubted. It may be cultivated in various culture media—namely, meat infusion, milk, gelatin, blood serum, and on the potato. It grows and multiplies in these culture media with great rapidity, at a temperature of from 60° to 107° F., and dies after a brief stationary period.

On what grounds do Koch and his associates base the conclusion that this bacterium has an essential causative relation to cholera?

1. That the organism is present in all well-marked cases of cholera. Koch failed to find it in no instance, the number of cases examined being one hundred.

Somewhat opposed to these observations by Koch are those by a commission composed of MM. Straus, Roux, Nocard, and Thuillier, who studied the disease in Egypt in August, 1883, by direction of the French Government. This commission found in twenty-four autopsies a micro-organism which was probably the bacillus described by Koch in the same situations within the small intestine. In all except three of these twenty-four cases this micro-organism was more or less abundant, the number exceeding that of any of the other varieties of bacteria. In three cases, however, only a very few were found, notwithstanding, as is stated in the report of the commission, diligent search was made for them. From the small number of these micro-organisms in these few cases, the members of this commission conclude that, quoting the language of the report, they "do not feel authorized to attribute a specific action to the microbe which they found in greater abundance in the majority of cases." It would certainly not be fair to attribute the fact of only a few bacilli having been found in these three cases to want of skill or to some defect in the materials or the methods of the microscopical examinations, although, naturally, a suspicion of this kind arises. Moreover, the report states that the commission were not acquainted with the *technique* followed by Koch. The discrepancy between the results of the examinations by the French commission and of those by Koch renders important further investigations by different competent and trustworthy microscopical observers.*

2. That the organism is not present in the healthy body nor in cases of diseases other than cholera. In a considerable number of cases of different diseases the results of examinations by Koch were negative as regards the presence of this parasite in either the intestine or its contents. It has been stated that a parasitic organism identical with the comma bacillus has been found by MM. Straus and Roux, and by others, in cases of other affections than cholera. I am not aware that in any instance as yet the presence of this parasite has been demonstrated by the culture-test except in cases of cholera. Obviously this test is essential in order to remove all doubt as to the accuracy of microscopical observations. Of course, further investigations in regard to the second ground on which is based the evidence of the parasitic doctrine of cholera are desirable, if

* For the report of the French commission, *vide* "Archives de physiologie normale et pathologique," Paris, 15 Mai, 1884.

not indispensable, before the doctrine can be considered to be positively established.

Within a few days, and after the greater part of this paper was written, a communication has appeared in the London "Lancet" (September 20th), by Surgeon-Major Timothy Richards Lewis, M. B., Assistant Professor of Pathology in the Army Medical School (Netley), in which it is stated that "comma-like bacilli, identical in size, form, and in their reaction with aniline dyes, with those found in choleraic dejecta, are ordinarily present in the mouths of perfectly healthy persons." The communication contains a comparison as regards the measurements of the cholera bacilli with those obtained from the secretions in the mouth in six specimens of each. It does not, however, appear that the culture-test of the faecal bacilli has been resorted to. If the statement by Lewis is correct, it can not fail to be speedily verified; and, if not correct, it will be disproved by other microscopical observers. Of course, if it is demonstrated that the bacilli of cholera are present in the mouths of healthy persons, although their presence in the intestinal canal may be characteristic of cholera, they are not the causative agents of this disease, but the disease simply furnishes an appropriate soil for their habitat. The intestinal mucous membrane in this disease is only a culture medium.

Should it be established that the comma bacillus is invariably present in cases of epidemic cholera, and that this parasite is never present except when this disease exists, it is logically certain that there is an essential pathological connection between this parasite and the disease. It does not, however, follow that the parasite is the cause of the disease. The grounds on which a pathological connection is certain are consistent with an opposite causative relation—that is to say, the disease may furnish local conditions essential to the growth and multiplication of the parasite, which, in this point of view, is secondary, and an effect, instead of being the cause of the disease.

A crucial experiment for determining a causative connection of the parasite with the disease is inoculation. If, as in the case of the *Bacillus tuberculosis*, the parasite of cholera, after a series of cultivations, is capable of producing the disease by inoculation, the proof of its being the essential cause is absolute. Koch reports failure in his efforts to obtain this proof. Different animals were inoculated repeatedly, but with negative results as regards the production of a disease having the characteristics of epidemic cholera. Similar efforts were made by the members of the French commission with the same negative result.

Continued experimental observations may lead to success in the transmission of the disease to animals. In the same number of the London "Lancet" (September 20) which contains the statement that the comma bacilli may be found in the secretions from the mouth in healthy persons, it is announced that two Swiss physicians, Rietsch and Nicati, who have been engaged in laboratory investigations of cholera in Marseilles, under instructions from the French Government, have succeeded in producing the disease in guinea-pigs by injecting the choleraic dejections into the duodenum. Of course if the success claimed by these ob-

servers is confirmed, it is proof demonstrative that the disease may be communicated, and it will then only remain to be demonstrated that the bacillus is a contagium vivum, by finding that inoculation therewith, after everything extraneous has been eliminated by cultivation, suffices to produce the disease.*

It is, however, to be considered that failure to obtain proof by the latter crucial experimental test by no means disproves the parasitic doctrine of cholera. All animals are not susceptible to the morbid action of micro-organisms which are known to be the causative agents of specific diseases in man. This is true of the *Bacillus tuberculosis*. Experiments have as yet failed to produce in animals typhoid fever by inoculation with the micrococcus which it seems quite certain is the causative agent in the production of that disease. The same is true of the bacillus of leprosy. On the other hand, certain infectious diseases which affect lower animals seem not to be communicable to man—e. g., Rinderpest and the pleuro-pneumonia of cattle. Quoting the language of Koch, "parasites have their special hosts; many kinds of animals have each its own tape-worm which can not develop in any other animal."

In the absence of the demonstration by inoculation of the parasitic doctrine of cholera, what ascertained facts go to sustain this doctrine?

A fact which speaks strongly in support of the doctrine has been already stated—to wit, that, reasoning by analogy, all infectious diseases may be logically considered as parasitic. Accepting the truth of this statement, the question is, whether the specific cause of cholera is the comma bacillus, or some other micro-organism not yet discovered. Now, as between the comma bacillus and other intestinal bacteria, with our present knowledge, the pathogenic claims of the former seem to be paramount.

Not accepting opposing statements, the correctness of which remains to be verified or disproved, and assuming the comma bacillus to be found exclusively within the alimentary canal, and only in cases of cholera, the pathological connection of the parasite with certain well-marked lesions of the mucous membrane of the small intestine is to be considered. These lesions are either due to the presence of the parasite, or they furnish a peculiar soil for its cultivation, in the latter point of view the parasite being a product of the lesions. Now, epidemic cholera, in all parts of the globe except India, is an exotic disease and of rare occurrence. In view of these facts, is it not vastly more improbable that the lesions precede the presence of the parasite than that the parasite exists prior to, and is the essential cause of, the lesions?

Koch's observations show that the comma bacillus grows and multiplies outside of the body, under favorable conditions of moisture and temperature, with very great rapidity, and that after two or three days the generations die out.

* In a more recent communication (quoted, from the "Deutsche medicinische Wochenschrift" for September 25th, in the Philadelphia "Medical News" for October 18th), Dr. Rietsch and Dr. Nicati profess to have produced cholera by the introduction of a pure culture of the bacilli into the duodenum of the dog after ligation of the ductus choledochus.

These observations are in harmony with those made in cases of cholera, and with the clinical history of the disease. Cholera is a disease remarkable on account of the brief duration of its career. The duration of the disease is not longer than that of the successive generations of the comma bacillus when cultivated outside of the body. The symptoms and pathological conditions occurring in cases of cholera after what is commonly known as the stage of reaction has taken place are, in reality, sequels of the disease. Now, the comma bacilli are found in the intestinal canal and in the dejections, in more or less abundance, early in the course of the disease. They are less abundant as the disease approaches the end of its career, and they disappear when the career of the disease is ended. These facts speak strongly for the parasitic doctrine.

It would go very far toward establishing the parasitic doctrine were it to be shown that the parasite had been introduced into the body prior to the development of cholera. Could this fact be established in a considerable number of instances, the proof of the doctrine would approximate to that afforded by inoculation. Some striking facts observed in India bearing on this point have been noted by Koch. It seems that in certain parts of India the water used in bathing, washing, cooking, and drinking is contained in tanks which are liable to become polluted by human excrement as well as by various kinds of filth. The occurrence of localized epidemics of cholera in the vicinity of these tanks had been a matter of frequent observation. Such a localized epidemic occurred during Koch's visit in India. About one hundred persons living in huts situated in the vicinity of a tank had been attacked with cholera. Examinations of the water in this tank showed the presence of the comma bacilli. The disappearance of these from the tank was coincident with the ending of the cholera epidemic. Examinations of water in other tanks were negative as regards the presence of these bacilli. That the water in the tanks gave rise to cholera had been previously the opinion of medical practitioners in India, and it had been observed that the substitution of pure water in certain situations had led to the disappearance of the disease.

In the endeavor to form a correct judgment concerning the merits of the parasitic doctrine of cholera, evidence should, of course, be weighed impartially, avoiding, if possible, any undue bias from preconceptions or first impressions. To accept a doctrine prematurely because it is new and attractive would be not less illogical than an irrational skepticism. A proper sentiment of conservatism should lead us not to commit our minds unreservedly until sufficient data have accumulated to serve as a solid basis for a judicial decision. That this decision will be in favor of the doctrine I believe to be probable. I may add that, in expressing this belief, I am not under the necessity of doing any violence to views heretofore expressed. I will venture to quote from the fifth edition of my work on the "Principles and Practice of Medicine," published in 1880, as follows: "If the germ-theory be adopted as affording the most rational explanation of the causation of other infectious diseases, this disease (cholera) certainly comes within the range of its application. Adopting this theory, the disease requires

for its production a specific germ or organism. Adopting the theory of indirect communicability, as just stated, germs are contained in choleraic excreta, but they require development under favorable conditions without the body in order to acquire infective power. . . . When the cholera-germ has undergone the requisite development, it may be transported in the atmosphere or carried from place to place attached to clothing, merchandise, etc. It is also intelligible that undeveloped germs may in like manner be transported, and find, in situations more or less distant from the places in which they are produced, the conditions favorable for their development."

It is not to be denied that there are difficulties in the way of reconciling the parasitic doctrine, as developed by Koch, with certain facts relating to clinical experience. The greatest of these difficulties relates to the diffusion and transportation of the contagium vivum. Assuming that the parasite is received into the body exclusively with the ingesta, it is difficult to explain the occurrence, not infrequently, of cases simultaneously, or in rapid succession, in different situations, more or less widely separated from each other, early after the occurrence of an epidemic invasion. It is difficult to reconcile the immunity from the disease of a very large proportion of those who are brought into long and close contact with cases of cholera, and the development of the disease, in a large proportion of cases, when there are no apparent means by which the parasite could be conveyed. These are difficulties somewhat analogous to those in the way of reconciling with clinical experience the communicability of tuberculous disease. Argumentatively, they are to be met, in either instance, by the question, Is the parasitic doctrine true or not? In other words, Is this doctrine substantiated by incontrovertible facts? If the answer be in the affirmative, difficulties, however great, in the way of reconciling the doctrine with clinical experience do not disprove the doctrine; they simply show that further knowledge is to be acquired before the reconciliation can be made evident. If the doctrine is true, the apparent discrepancy between it and clinical experience is to be laid to the account of our limited knowledge, and should not lead us to distrust the doctrine. To remove any discrepancy should be the object of continued investigations.

Assuming the truth of the parasitic doctrine, what is its bearing on the treatment and on the prevention of epidemic cholera? This question is of pressing practical importance at this time, when an invasion by this disease at any moment may be looked for.

The destruction of the parasite within the intestinal canal by any of the parasitocides which are found to destroy it outside of the body appears impracticable. It seems that the anti-parasitic agents with which we are acquainted, introduced into the intestinal canal sufficiently to prove toxic to the parasite, must prove toxic to the patient. Here, however, is a field for investigation by no means as yet fully explored, and it is possible that an agent may be found capable of destroying the parasite without risk to the patient.

The parasitic doctrine does not, of course, invalidate what clinical experience has taught respecting the treatment of cholera. And clinical experience has taught that there

is no disease with greater certainty controlled at the outset than this. The controlling remedy, *par excellence*, is opium. Let opium, conjoined with rest of the body and of the digestive organs, be judiciously employed before the characteristic choleraic dejections occur, and the further development of the disease is prevented with almost absolute certainty. Let this treatment be promptly resorted to as soon as choleraic dejections have taken place, and, in a large proportion of cases, the disease is arrested. I make these assertions, not alone on the testimony of others, but on a pretty large experience in epidemics which have already occurred in this country.

What is the *modus operandi* of opium in this disease? Does it act by producing a narcotic effect on the parasite? Does it lead to the destruction of the parasite by an effect upon either the secretion or the absorption of bile, preventing thereby alkalinity of the intestinal contents, which alkalinity, according to Koch's observations, is essential for the life of the bacillus? Is its efficacy due to its effect upon the peristaltic movements of the intestine? I am not prepared to answer, and it would be useless to discuss these and other questions which might be raised. We have here an instance, which is not rare, of an important therapeutical truth, based on clinical experience, which we can not satisfactorily explain, but the claims of which, as regards medical practice, are not any the less imperative because, in the present state of our knowledge, it is inexplicable.

The bearing of the parasitic doctrine on the prevention of cholera has more apparent importance than the bearing on the treatment.

In the first place, it is probable that the recognition of the bacillus in the dejections will enable us to determine positively the nature of the disease in cases which precede its epidemic prevalence. As is well known, prior to and during the diffusion of the disease, with its well-marked characteristics, cases of apparently simple diarrhoea are common. There is reason to believe that the parasite is the morbid agent in these cases. Observations with reference to this point are desirable. Assuming that cases of so-called cholera have the same ætiology as cases of true cholera, the occurrence of the former will seem to explain, in a measure, the diffusion of the disease. As foci for the production of the contagium, they may be not less instrumental in the diffusion of the disease than cases of fully developed cholera. It follows that measures for the destruction of the parasite after it leaves the body are not less important for the prevention of the disease in all cases of cholera than in cases of cholera. This view of the prophylaxis is not altogether new; but its importance will be enhanced by the discovery that in cholera, as in cholera, the dejections contain the parasite. Moreover, the presence of the parasite both in cholera and in cholera will settle definitively the question, heretofore much discussed, as to the pathological identity of the two affections.

As to the preventive measures to be employed, if the parasitic doctrine is true, the direction which these should have is sufficiently clear. Complete destruction of the parasite directly it leaves the body is the object to be effected. If this object is thoroughly effected, every case of cholera

is rendered sterile as an agent in the propagation of the disease. Koch's observations have shown that the comma bacillus is destroyed by desiccation, and that it is rendered torpid, but not destroyed, by cold. After a few hours, if moistened cloths containing the parasite are allowed to dry, they become innocuous as fomites. This is an important and suggestive fact. But the process of drying, even when expedited as much as possible, involves some loss of time. If articles soiled by dejections are not immediately burned, they should, without a moment's delay, be subjected to an efficient disinfectant. It suffices, as regards quarantine regulations, that clothing or merchandise from places in which the disease prevails be either disinfected or detained long enough to avoid all danger from the importation of the parasite.

The local conditions under which the parasite thrives outside of the body have as yet been insufficiently studied by means of microscopical observations. Observations, however, have shown that filth of all kinds promotes the diffusion of the disease.

There is another field for study concerning which accurate information is wanting—to wit, the conditions within the body which favor the colonization, growth, and multiplication of the parasite. Koch failed to find the parasite in the stomach except in a very few instances, and in these it was supposed that the contents of the intestine had regurgitated. He infers, therefore, that the acidity of the gastric fluids is fatal to the parasite, and that it passes into the intestine with safety only when the stomach is in an abnormal condition. Clinical experience, however, hardly sustains the conclusion that disorder of the stomach precedes the advent of cholera. In many, if not most, instances persons are attacked by the disease when in apparently perfect health. That a peculiar susceptibility or a predisposition is an important, if not an essential, factor in the ætiology of the disease, is not improbable, but our present ignorance of the conditions constituting this susceptibility or predisposition is as complete as in regard to tuberculosis, and also other infectious diseases.

In connection with these remarks on the prevention of cholera, I desire to call attention to the history of the disease in this city in 1866 and 1867. In these years were exemplified the measures by which an epidemic of cholera may be "stamped out." The stamping out in this city was by measures which are in accordance with the parasitic doctrine of the disease, and affords strong, if not conclusive, proof of the truth of this doctrine.

In anticipation of the prevalence of cholera in 1866, the Metropolitan Board of Health, which had been recently organized, adopted a system of prompt and thorough disinfection whenever and wherever cases of the disease might occur. Sanitary inspectors were appointed, some of whom were constantly on duty at the central office of the Board of Health, prepared to visit at once cases reported as cases of cholera and to decide upon the diagnosis. A disinfecting corps was organized, consisting of soldiers who had been in the recent civil war. They were under the charge of one who had served as an officer in the war. Wagons loaded with disinfecting material were in readiness, together with

horses in harness, at a moment's notice. The system was analogous to that of the Fire Department. The object was to disinfect the houses and the surroundings wherever a case of cholera occurred, precisely as it is an object of the Fire Department to extinguish a conflagration as expeditiously as possible. All the arrangements were under the supervision and direction of the sanitary superintendent, the late lamented Edward B. Dalton, an officer of rare executive ability. What was the result of these measures to prevent the diffusion of cholera? Cases of the disease occurred, during the summer and autumn of 1866, in 362 houses more or less widely separated from each other. In no instance did the disease extend proximately beyond the house in which a case or cases occurred.

In 1867 twenty-seven deaths from cholera occurred in the city of New York, five cases occurred in the city of Brooklyn, and eighteen at the military post in the harbor of New York. The measures for stamping out the disease were those employed in 1866, and the disease did not prevail as an epidemic. For further details in reference to the history of the disease in this city and neighborhood in 1866 and 1867, I refer to the reports of the sanitary superintendent and of the statistical secretary (the late Elisha Harris), which are contained in the volumes published by the Metropolitan Board of Health for those two years.

My belief is that never before nor since, in any other part of this or in any other country, have measures for the prevention of epidemic cholera been devised so scientifically, so thoroughly carried out, nor so successful in the results as those employed by the New York Metropolitan Board of Health in 1866 and 1867. The facts pertaining to the history of cholera in this city during these two years, as I have said elsewhere, are of momentous importance. They should be cited throughout the world as evidence that cholera is a disease which may be stamped out by efficient sanitary measures efficiently employed. It is my belief that in Marseilles, Toulon, and Naples—which have been lately scourged by this disease—the progress of the epidemic could have been arrested by the measures which were demonstrated to be effectual in this city in 1866 and 1867, and that thousands of lives might have been thereby saved. I believe firmly that, should the disease be again introduced into this country, to decide whether or not it shall prevail as an epidemic lies within the power of preventive medicine.

In conclusion, let me say a few words in reference to the study, not alone of cholera, but of other infectious diseases. We are entering upon a revolutionary period in the progress of medicine. Hereafter this present period will be cited as the commencement of an important era in medical history. The progressive advancement of our knowledge of the causes of the infectious diseases will revolutionize not only aetiology and pathology, but therapeutics. A new impulse and direction will be given to experimental researches and to clinical observations as regards the treatment of these diseases. Now, shall the medical profession of our country actively participate in the study of micro-organisms and their pathological relations, or, on the other hand, be content to await passively developments by the labors of active workers in other countries? A large field

is open to those who desire to engage in this study. At the present time, in addition to phthisis and epidemic cholera, typhoid fever, malarial fever, and pneumonic fever are special subjects for investigation. Other infectious diseases—the eruptive fevers, typhus fever, yellow fever, cerebro-spinal fever, dysentery, influenza—remain to be studied. Our country offers ample opportunities for the study of these diseases with a view to discover and investigate the parasitic organisms which—as there is reason to believe—are essential factors in their causation. Is there lack of ability on this side of the Atlantic to prosecute this study? If not, what is lacking? The answer is, self-reliance and energy; self-reliance leading American pathologists to become not merely followers, but competitors, in this field of study, and energy sufficient to overcome obstacles. It must be granted that in this country in the way of original investigations there are difficulties which do not exist to the same extent in other countries. Our Governments offer neither encouragement, nor rewards, nor adequate facilities for the development of knowledge in a field of study which, more than any other, is intimately connected with life and health. Incitements must be derived from the attractiveness of the study, from a desire to acquire and promote useful knowledge, together with a laudable ambition for professional distinction. Private beneficence must take the place of governmental aid. The recent munificent gift by Andrew Carnegie, for a building to be devoted to physiological and pathological laboratories, is an example which, it is to be hoped, will be followed by others who, like him, desire to contribute to the progress of science and the welfare of humanity.* With sufficient self-reliance and energy, together with the co-operation of our philanthropic fellow-citizens, this city of New York may be made celebrated as a place of resort for instruction as regards the methods and the results of pathological study, and also for having originated some of the discoveries which are to affect incalculably the science and the practice of medicine.

THE THERAPEUTICAL EFFECTS OF THE INTERNAL ADMINISTRATION OF HOT WATER IN THE TREATMENT OF NERVOUS DISEASES.

By AMBROSE L. RANNEY, A. M., M. D.,

PROFESSOR OF APPLIED ANATOMY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

(Concluded from page 427.)

THE EFFECTS OF THE TREATMENT.

1. On drinking a goblet of hot water for the first time, a sense of warmth within the stomach will be produced, unaccompanied with nausea. This is not the case with warm water, since emesis often follows its introduction into the

* Since this paper was in type, it has been announced that Mr. William H. Vanderbilt has given to the New York College of Physicians and Surgeons half a million of dollars. Great as will be the immediate beneficial results of this magnificent gift, we may hope for still greater benefit from it as tending to give to private beneficence a direction toward the promotion of medical knowledge and medical education.

stomach. Hot water increases downward peristalsis; warm water reverses peristalsis and induces vomiting. Eructations of gas from the stomach commonly occur within a few minutes after the first dose of hot water. This effect may persist for some weeks. Excessive eructation indicates that fermentation of food occurs after eating, from defective alimentation.

2. The *skin* soon shows the effect of the heat. A gentle glow with a tendency to perspiration is developed rapidly. This is diffused over the entire body. Coldness of the extremities is often very much benefited, and in a short time, by this treatment. The circulation of the body appears to become more uniform. It is rational to suppose that the viscera are often thus relieved of engorgement, and aided in the performance of their proper functions. Perspiration so induced is unquestionably associated with an increased supply of blood to the skin, since it is accompanied with a sensation of increased warmth.

3. The *kidneys* exhibit marked effects of this treatment early. Almost immediately, the quantity of urine is increased. It is usually improved also in its proportion of solid ingredients, provided the organs are inclined to be sluggish. If, on the other hand, diabetic symptoms exist, the specific gravity is frequently modified and the quantity reduced. One patient, who was lately placed under my care with marked saccharine diabetes and symptoms of cerebral hyperæmia of a severe type, has been perfectly cured by hot water, restricted diet, and simple tonics. He had previously tried all the known remedies (and a diabetic diet as well) for years without benefit. I was called in consultation about a year ago in a similar case, and the patient recovered under this treatment. He had symptoms of an alarming character and had previously found no relief. Both of these cases were, in my opinion, of neurotic origin. The head symptoms, which were very marked in both, disappeared under the same treatment, although the actual cauterly had been tried thoroughly and had failed to arrest them.

4. The *accessory organs of digestion* (the liver and pancreas) seem to be stimulated by the internal use of hot water. Gradually, under its continued use, the bowels move regularly and the feces eventually become soft and yellow in color.* Flatulence and constipation are enumerated as things of the past. I have known hæmorrhoids of long standing to disappear under this treatment. Chronic diarrhoea was thus arrested by me in one instance. It was apparently due to extreme nervous debility.

5. The *nervous system* seems to be profoundly impressed by a prolonged use of this agent. Especially is this the case among that class of patients who suffer from the effects of hyperæmia and anæmia of the brain and of the spinal cord and spinal nerves. Perhaps there are no greater sufferers than are found among this class. I have at present under my care a lady who, for twenty years, has been confined almost constantly to her house from neuralgic attacks which have withstood all medicinal agents. Under the use of hot water and the meat diet (she is somewhat fleshy),

the symptoms have shown a marvelous improvement within one month. Her paroxysms are already very much diminished in their severity, and are comparatively infrequent. I hope to see them disappear entirely.

I have at present under my charge several patients suffering from locomotor ataxia. I am treating them by the internal administration of hot water, in conjunction with the actual cauterly, nitrate of silver, and the iodide of potash. Sufficient time has not yet elapsed, since the hot water was prescribed, to state positively that permanent benefit has been derived from it, but I am convinced that very marked improvement has followed its use in two cases. It is my intention to published subsequently the records of all of these experiments. Thus far the efforts of neurologists to arrest progressive sclerosis of the posterior columns of the spinal cord have been unsatisfactory, and the question of a direct dependence of this condition upon a syphilitic taint must probably (to my mind) be decided in the negative.* Pathological research to date has not aided us in determining its ætiology; hence its treatment, as yet, is purely empirical, and experimentation regarding its cure is particularly to be desired. I can only say in this connection that one patient, whom I have at present under observation, came to me unable to walk, save by the aid of two canes and a body servant. Already one cane and the servant have been dispensed with, and the patient suffers less than he did from anæsthesia of the limbs and lightning pains. Another, who had diplopia, and marked incoordination of movement, is no longer troubled with imperfect vision and walks with more confidence. I am aware that similar results have been recorded without recourse to the hot-water treatment, but in these cases it seems to have been a marked factor in the amelioration of the symptoms. If it could be proved that this agent exerts a remedial influence upon gray degeneration of the spinal cord, what a boon would be conferred upon thousands who are now suffering without much hope of cure.

The paucity of literature upon this therapeutical agent renders statistics collected from the experience of others impossible.

This paper is necessarily but a record of my own experience. I may be pardoned for apparent egotism, therefore, if I refer here only to cases which have been intrusted to my care.

Within the past five years I have succeeded in curing three cases of gastralgia, where the paroxysms have been frequent and terribly severe for a long time. In one of these (that of a gentleman of great will and courage) the severity of the pain would frequently cause fainting. In another (that of a lady of forty-five years of age) the gastric pain had been constant for years, and gastric cancer had been suspected to exist.

Patients with neurasthenia are almost invariably benefited by the hot-water treatment. In many instances I have

* The statistics upon which syphilis has been classed among the ætiological factors of ataxia are open to severe criticism. Our present knowledge of the morbid changes produced by syphilis upon the cerebro-spinal axis does not appear to sustain the view that systematic lesions of the cord are ever directly produced by it.

* At first the feces are made very black by the washing down of the bile.

witnessed a rapid disappearance of all the abnormal nervous phenomena. Two cases of local anæmia of the brain, with transient aphasia, have been lately observed by me. Both patients recovered under the hot-water treatment and tonics. The latter had been tried alone in one of them, for some premonitory symptoms, without marked benefit.

To cite all of the cases in which I have employed this agent, either alone or in combination with other methods of treatment, would exceed the limits of this article. I believe, however, from my observations to date, that the use of hot water will prove of great value in neurasthenia and some of the functional nervous derangements.

My observations of its effects upon epilepsy and chorea are as yet imperfect, and therefore lead me to no positive conclusions.

I think it not impossible, moreover, that the continued use of this therapeutical adjunct may tend to modify, if not arrest, some of the progressive degenerations of the cord. I am not prepared to make any assertion to that effect, however, although I am testing it in some aggravated cases, in connection with the use of the cautery and medicinal agents. This field has been previously referred to.

THEORY OF ITS ACTION.

It is a temptation to speculate in regard to the probable channels through which the effects of hot water upon the system are exerted. To my mind, the neurotic theory is the most plausible. I believe that the nerves of the stomach, and possibly the solar plexus (the ramifications and connections of which with the central nerve-centers are not fully determined), are directly influenced by the heat introduced into the empty organ.

Mayer and Pribam have already shown that electrical and mechanical irritation of the walls of the stomach can produce a reflex contraction of the cerebral vessels. Kussmaul has demonstrated that similar effects may follow faradization of the cervical sympathetic. Nothnagel and Loven have proved that irritation of peripheral nerves exerts a marked effect upon the arteries.

The solar plexus lies immediately behind the stomach, and is connected with all of the abdominal viscera. The splanchnic nerves of either side, and probably the terminal filaments of the right pneumogastric nerve, enter into its formation. It is therefore connected directly with the brain and the main sympathetic cords, and indirectly with all of the organs of the body. It is the most important of all the sympathetic plexuses, as well as the largest. Why are we not justified in believing that the effect of stimulation of this plexus, by heat through the stomach, will accomplish that which electrical stimulation of the stomach itself has been proved to attain? Are we not warranted in attributing the warmth of the skin, the perspiration, the increased activity of the kidney, the stimulation of downward peristalsis, and the other effects of this agent, to a remote influence upon the vaso-motor nerves or their centers? If so, why is the view irrational that cerebral and spinal hyperæmia and anæmia may be controlled and brought to the normal standard by the same means?

POINTS IN ITS FAVOR.

This method of treatment has certainly one thing in its favor that few possess—viz., it is harmless. Because its remedial effects are slow in some cases, it is no proof that they are not doubly permanent. Are we not convinced daily that many of the more common nervous diseases are obscure in their origin, and that the removal of the cause might hasten recovery, if we could only detect it?

Most of our nationality chill their stomachs with ice-water between meals and during the act of eating. Who would think of feeding a horse, and placing a bucket of ice-water by his side? The question may well be raised if this one habit alone has not done more harm to the nervous systems of men than tobacco or alcohol, the use of which is mentioned in all text-books as an ætiological factor in nervous diseases.

I believe that the success of the hot mineral waters, as consumed at the famous springs of this country and Europe, for chronic diseases, depends more upon the employment of internal heat as a therapeutical agent than upon the mineral ingredients of the waters themselves. I do not advance this view to disparage the medicinal qualities of these waters, but to bring into prominence the view that heat, restricted diet, and enforced mental and physical rest, are probable factors in the remarkable cures that are brought about by their use.

In anticipation of argument, I might say that I am well aware that this agent is not a new one, and that it is not always followed by the effects enumerated. Who of us, however, has not met, in professional experience, cases where opium has failed to produce sleep? Yet who doubts that it is one of our chief hypnotics? I lately encountered a case where sixty grains of morphine were consumed daily, by the mouth, and constipation had never existed. Yet who would dispute the statement that this drug tends, as a rule, to restrain the free action of the bowel, even in small doses? Because the public are to-day crazed over hot-water drinking, and are asserting for it medicinal virtues to which it has no title, are we justified in denying for it a fair trial in those diseased conditions that withstand the routine medicinal treatment recommended by text-books? We have undoubtedly yet to learn exactly to what extent it exerts a remedial influence upon the kidneys, digestive organs, vascular apparatus, skin, and the principal nerve-centers, but that it is potent in some cases can not be disputed. *No pretension is made for it here as a panacea.*

Again, it may be argued that, in some of the cases to which I refer, this agent has been employed in conjunction with restricted diet, the actual cautery, the internal administration of tonics, etc.; and that some of the benefits may justly be attributed to these factors in the treatment. To this criticism I would reply that, in some of these cases, the hot water has not been used until the other agents spoken of had been thoroughly tried, and that improvement has been markedly hastened by adding it to the previous treatment. In one diabetic case reported, the symptoms were not controlled by drugs or restricted diet; but the excretion of sugar ceased in a few weeks, when hot water was ordered as an adjunct to a diet from which all starchy and saccharine foods were expunged.

A third class of critics, whom I as well as most of those present have often encountered in argument, are those who expect immediate results, and who throw every agent overboard in case they fail to get results as promptly as they had expected. They argue that patients will not take any form of treatment with regularity which does not show rapid results. Admitting for the sake of argument (and on no other ground) that there may be a shadow of truth in this statement, I would reply that (provided the patient is prepared at the first visit for slow results, and informed in respect to its action) this objection can be overcome. I would suggest, furthermore, that the use of hot water does not preclude the employment of opiates and other drugs, when the exigencies of the case seem to demand them. One reason why this agent may not be productive of good results, even in favorable cases, is that it is not given systematically and in accordance with the rules previously suggested. Hot water is unquestionably not conducive to health, if poured into the stomach without restrictions as to quantity and the proper time for its administration.

CONCLUSIONS.

In summary, I would urge a thorough trial of this therapeutic agent by the profession on the following grounds:

1. It is harmless, if properly administered. A degree of temperature that can be endured by the mouth will not impair the integrity of the stomach. Absurd as it may seem, I have heard this argument used by men of intelligence with every appearance of sincerity. Many of us drink coffee and tea at an equally high temperature, and in as large quantities, as are compatible with the hot-water treatment.

2. Its effects are comparatively uniform, provided it be given for a sufficient period. Exceptions prove a rule. Isolated cases may be occasionally encountered where the results as stated do not occur.

3. It seems to exert a curative influence upon many of the chronic diseases that influence and disturb the proper assimilation of food. Some of these are important factors in the development of nervous derangements. I restrict my statements for hot water as yet chiefly to the cure of these diseases, because I have not scientific data upon which to base a broader statement. Subsequent investigation can alone decide to what limits the remedial use of this agent should be restricted.

4. It appears that the curative influence of hot water is not usually transient. In many of my cases the symptoms have shown no tendency to return when once checked by its use, provided that the patient's indiscretions do not lead to a relapse.

5. It may be employed as an adjunct to all recognized methods of treatment, without detriment to the patient.

6. It exerts a marked influence upon vascular disturbances of the nerve-centers. Especially is this the case, in my experience, with those subjects that suffer from cerebral hyperæmia and anemia. I have seen some remarkable results follow the protracted use of the hot-water treatment in headache, vertigo, neuralgia, insomnia, and other conditions produced by vascular disturbances.

7. In diabetes, and in some kidney derangements, I have seen the most happy effects follow the internal administration of hot water. Its action as a diuretic is quite remarkable in some cases. It seems also to influence the secretion of urinary salts, since the specific gravity is modified often to a marked degree. The specific gravity of the urine is my guide in regulating the quantity of hot water for daily consumption.

8. As a laxative, hot water has a slow but decided action. The feces are at first rendered black, from an excess of bile, but they gradually change to a yellow color, and become more like that of the infant. It seems to be a justifiable deduction, therefore, that the functions of the accessory organs of digestion are made active by its use, and brought to the standard of health.

9. The skin is stimulated by the use of this agent, and the cutaneous circulation is apparently rendered more uniform. I have seen the hue of the skin in disease altered by it, and eruptions of a chronic character markedly benefited.

10. From a few experiments which I have made with reference to the effect of this agent as a preventive of seasickness, I am led to believe that it should be employed for from four to six weeks preceding an ocean voyage, in accordance with the rules given earlier in the evening.

In conclusion, I would state that, if I have been led to express views that may appear extreme to many, it is because my convictions are based upon clinical observations of no inconsiderable magnitude. I have seen my previous failures in treatment turned by this agent into brilliant successes in some instances. In others, symptoms have been ameliorated by the use of hot water more rapidly than by methods of treatment universally recommended by text-books. To what limits the value of this agent will be restricted, as a therapeutical adjunct, the results of collected observation and experience to date can not fully determine. I shall await with interest the published results of the experience of others, who have doubtless employed this agent in various forms of chronic diseases, and especially those bearing upon the department of neurological medicine.

156 MADISON AVENUE.

A FEW CLINICAL FACTS REGARDING COCAINE HYDROCHLORATE, THE NEW ANÆSTHETIC.

By LE ROY POPE WALKER, M. D.,
RESIDENT SURGEON, NEW YORK EYE AND EAR INFIRMARY.

THE following cases are a few, selected from a large number, that have come under my observation during the past week:

CASE I (Service of Dr. W. F. Mittendorf).—M. T., female, aged twenty-one, highly nervous. Had a tenotomy of left internal rectus done two years ago for convergent squint. She has heart trouble. The operation was performed without ether, and she states that the pain was so great that "a dozen young doctors," who were present at the operation, could scarcely hold her. The result of this tenotomy was very unsatisfactory. She came "prepared to take ether, even at the risk of her life,"

as she said. Cocaine (two per cent.) was instilled, about twelve drops. After an interval of about five minutes (was not timed) a very thorough tenotomy was made, taking little more than one minute. The patient did not resist, and experienced no pain, "only a little pressure" (from speculum).

CASE II (Service of Dr. Mittendorf).—J. R., male, aged eight. Had a double tenotomy done six days ago, the sutures remaining. Not wishing to give ether or chloroform, a few drops of cocaine (8-10) were instilled. After five minutes, speculum introduced without resistance and sutures removed. Complained of no pain.

CASE III (Service of Dr. Mittendorf).—M. R., male, aged thirty-nine, received a contusion of cornea, which resulted in a large superficial and painful ulcer. Atropine and warm compresses failed to give relief, and use of cocaine was resorted to; one drop every half hour. The relief was perfect but temporary, and the cocaine had to be used for thirty-six hours until relief was obtained. Ulcer healed in this time.

CASE IV (Service of Dr. M.).—J. P., male, aged fifteen, traumatic cataract. Had been needed before without ether and resisted very much. Ten drops of cocaine instilled, and, after interval of eight minutes, permitted insertion of speculum and attachment of forceps to conjunctiva, without a symptom of discomfort. Needling completed without pain or inconvenience.

CASE V (Service of Dr. M.).—Female, aged eight, congenital cataract; highly nervous, and much frightened. After two instillations of cocaine, speculum introduced with a little resistance (fright), and permitted needling to be finished, in very good order. Said afterward that it caused no pain.

CASE VI (same service).—P. F., male, aged fifty-seven, secondary cataract. After one instillation (cocaine) cornea and conjunctiva anæsthetic. Dissection of capsule completed without pain.

CASE VII (same service).—J. W., male, aged five, convergent squint, very nervous. After two instillations, interval three minutes, permitted introduction of speculum, and completion of other steps of operation (tenotomy) with a little resistance, but it was due more to fright than to pain. Said afterward that he had not been hurt.

CASE VIII (same service).—M. McD., female, aged eleven, iris caught in old cicatrix. After two instillations, operation for iridectomy completed very quietly, and without resistance. Experienced no pain.

CASE IX (same service).—W. W., male, aged thirty-one, had a small piece of emery in cornea. Eye very much irritated by former attempts of fellow-workmen to remove it. After using eight to ten drops of cocaine, cornea was so anæsthetic that he did not feel scraping of the needle used to remove it.

CASE X (out-door service).—A. F., male, aged thirty-five; foreign body imbedded in cornea. Eye very sensitive. Patient resisting greatly any attempt to open lids. Two instillations of cocaine, interval two minutes (timed). Seven minutes after first instillation, cornea perfectly anæsthetic, as also conjunctiva. Permitted foreign substance to be removed, and conjunctiva to be grasped with fixation forceps, without wincing.

CASE XI (out-door service).—T. B., male, aged forty; extensive burn of cornea and conjunctiva from hot metal. Eye and lids exceedingly sensitive, and would not permit them to be touched. Cocaine, ten drops, instilled, and, after an interval of six minutes (timed), allowed thorough examination to be made. Said he was entirely free from a pain that had been intense for two days.

CASE XII (out-door service).—S. R., male, aged twenty-five; traumatic keratitis. Had been injured by a fragment of metal. Could not face the light. Great pain, photophobia, and lachry-

mation. Cocaine instilled (8-10 drops) once, and after five minutes (timed) could open eye, and said he was free from pain.

CASE XIII (out-door service).—W. McC., male, aged thirty; foreign body imbedded in cornea. Cocaine instilled twice, interval three minutes. Seven minutes after first instillation, cornea completely anæsthetic as well as conjunctiva. Removal of foreign body absolutely without pain, although it was firmly imbedded, and a good deal of epithelium was scraped off.

CASE XIV (out-door service).—C. C., male, aged sixteen; foreign body in cornea. Very nervous and apprehensive. Cocaine instilled once. In three minutes (about) cornea anæsthetic. Foreign body removed without resistance, and with no pain.

In five cases of sensitive throat I have been enabled not only to use the mirror, but to prick the mucous membrane with a sharp-pointed instrument without pain and with very little "gagging."

COCAINE HYDROCHLORATE, THE NEW LOCAL ANÆSTHETIC.

By J. HERBERT CLAIBORNE, JR., M. D.,

CLINICAL ASSISTANT TO THE CHAIR OF OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC.

THE two patients whose cases are herewith reported, in which the new local anæsthetic—the hydrochlorate of cocaine—was used, were operated on by Professor Gruening, before the eye clinic of the New York Polyclinic, at Mount Sinai Hospital:

CASE I.—A colored woman, aged forty-five, with double over-mature cataract, was placed upon the operating-table, and three drops of a two-per-cent. solution of cocaine hydrochlorate were instilled into each eye every five minutes for fifteen minutes. Twenty minutes after the first instillation the speculum was introduced into the right eye, the conjunctiva was seized with a fixation-forceps, and a large section was made with von Graefe's cataract-knife, without any shrinking or expression of pain on the part of the patient. While the iridectomy was being done, she winced and gave a slight expression of pain. The left eye was then operated upon with equally satisfactory results, but the pain of the iridectomy seemed less in the left than in the right eye.

CASE II.—The patient was a German, fifty years old, with glaucoma of the right eye, attended with excessive tension and ciliary staphyloma. He was blind in the glaucomatous eye. Four drops of the same solution as had been used in Case I were instilled into the right eye every five minutes for twenty minutes. Thirty minutes after the first instillation, the sound eye being uncovered, the speculum was introduced and the fixation-forceps applied. The patient objected strenuously to the speculum; in fact, squeezed it out, and shrank from the application of the forceps. A pad of borated cotton was then placed over the sound eye, the speculum was introduced, the fixation-forceps was applied, and the section was made, without any expression of pain from the patient. Immediately before the second attempt, four more drops of the solution were instilled into the eye. The iridectomy, in this case also, was attended with pain.

In Dr. Gruening's office, after the instillation of two drops of a two-per-cent. solution, a foreign body was removed from the cornea of a hyperæsthetic man, without pain.

In a case of episcleritis, after an instillation of the same sort, there was marked diminution of sensibility in the conjunctiva, although there was still pain on massage.

In the first three instances the hydrochlorate of cocaine certainly accomplished all that has been asserted for it, viz.: anæsthesia of the conjunctiva and cornea. In the case of episcleritis, the anæsthesia, although marked, was not so complete as in the other cases. Whether or not its anæsthetic effect is always diminished in the case of the tissues mentioned when they are in a pathological condition, remains to be seen.

In the case of the woman with cataract, there was less pain caused by the iridectomy in the left eye than in the right; and the left eye, as has been stated, was the second one to be operated on.

It is possible that the anæsthetic effect of the drug might, by imbibition of the solution, have reached the iris tissue in the left eye, as there had been an opportunity for absorption to go on for a longer time.

The solution used in these cases was made by Eimer & Amend, of New York.

The honor for this new and brilliant addition to ophthalmology is due to Dr. Koller, of Vienna, a young man who is still pursuing his studies in that city.

Book Notices.

Elements of Practical Medicine. By ALFRED H. CARTER, M. D., Lond., M. R. C. P. L., etc. Second edition. London: H. K. Lewis, 1883. Pp. xvi. 427.

The Same. Third edition, revised and enlarged. New York: D. Appleton & Co., 1884.

ALTHOUGH this work does not profess to be a complete treatise on the practice of medicine, it is too full to be called a compend; it is rather an introduction to the more exhaustive study embodied in the larger text-books. An idea of the degree to which condensation has been carried in it can be gathered from the statement that but twenty-one pages are occupied with the diseases of the circulatory system. If the reader gets the impression that the physical signs are given somewhat too meagerly, it is to be said that, by way of compensation, the symptomatology in general is considered with admirable perspicuity and good judgment. The author recognizes a presystolic heart murmur, and says that, while it is almost always associated with organic heart disease (mitral obstruction), it is occasionally found in conjunction with mere functional dilatation of the left side of the organ. He does not seem to have noticed Flint's explanation of the occurrence of such a murmur with aortic regurgitation and no mitral disease.

Leucocythæmia is dismissed with one page—wisely, perhaps, since we know so little about it; and of that other almost unknown quantity in medicine, scrofula, the author has with equal prudence abstained from saying much. He admits such a condition as scrofulosis, but thinks it has no necessary connection with tuberculosis. He is a believer in the germ-theory of disease, and speaks of Koch's investigations and discoveries as very important, to him almost conclusive.

Notwithstanding the condensed make-up of the book, it is quite comprehensive, including even cutaneous and venereal diseases. It contains much valuable information, and we may add that it is very readable.

Clinical Notes on Cancer, its Ætiology and Treatment. With special reference to the Heredity Fallacy and to the Neurotic Origin of most Cases of Alveolar Sarcoma. By HERBERT L. SNOW, M. D. (Lond.), etc., Surgeon to the Cancer Hospital, Brompton. London: J. & A. Churchill, 1883. Pp. 96.

In this little book the author has set forth some exceedingly interesting and valuable facts regarding cancer, drawn from several years of clinical study. The work is not pathological, but clinical, and will therefore be found useful by the general practitioner. Considerable vigor is displayed in the demolition of what the book calls the "heredity fallacy," and the idea of a cancerous diathesis, or "a peculiar habit or condition of the body, of which the malignant deposit was only the local manifestation"; and a chapter is devoted to the neurotic origin of alveolar cancer. The author's ideas upon the latter subject are tersely stated in the following passage: "I may mention (as pointing out its diagnostic value, and how one learns to expect it in these cases) that several times I have been at first considerably puzzled when a patient has appeared with supposed uterine cancer, yet without any previous worry, trouble, or hard work. An examination has solved the mystery, showing the rectum to be the seat of disease."

The work is full of valuable hints, and will repay a careful reading.

On Malignant Disease (Sarcoma and Carcinoma) of the Larynx. By HENRY T. BUTLIN, F. R. C. S., Assistant Surgeon and Demonstrator of Diseases of the Larynx, St. Bartholomew's Hospital. London: J. & A. Churchill, 1883. Pp. 64.

THIS is a continuation of a previous work, by the same author, on sarcoma and carcinoma. Having exceptional opportunities for the study of tumors, he has endeavored to write a "tolerably complete life-history of sarcoma and carcinoma," assuming as a basis of distinction between the two diseases that the one is of connective-tissue, the other of epithelial origin. In order to limit the wide scope of the work and enable him to perform it piecemeal, and yet furnish each separate fragment in a complete form, he has thought best to select one particular organ or tissue, and work out the life-history of the malignant tumors of that organ or tissue, before proceeding to another.

The testis, the bones, the tongue, the œsophagus, and the tonsils have already been studied, and in this volume the work is made to include the larynx. The author has made a careful study and analysis of all trustworthy cases obtainable, and has considered the diseases from both a microscopical and a clinical standpoint, including the question of the propriety and advisability of extirpation of the whole organ. The book shows evidence of earnest and well-directed work, and can not fail to prove an important addition to the literature of malignant diseases.

BOOKS AND PAMPHLETS RECEIVED.

The Brain and the Nerves; their Ailments and their Exhaustion. By Thomas Stretch Dowse, M. D., F. R. C. P. E., Fellow of the Medical Society of London, etc. New York: G. P. Putnam's Sons, 1884. Pp. 150. [Price, \$1.50.]

NEW YORK, SATURDAY, OCTOBER 25, 1884.

MR. VANDERBILT'S GREAT GIFT TO THE COLLEGE OF
PHYSICIANS AND SURGEONS.

In view of the singular unanimity with which—at all events, up to within a very short time past—men of wealth have ignored medical colleges in their benefactions, there are few things, we imagine, likely to take the profession so much by surprise as the news that a single individual had given half a million dollars to one of those institutions. Yet such is the announcement that we have the pleasure of making to our readers. Mr. William H. Vanderbilt has enriched the College of Physicians and Surgeons in the city of New York by a gift of that sum. By so doing he has conferred a boon not only upon the college, not only upon the profession of medicine, but also, and chiefly, upon the community; for the fruition of his generous deed will show itself most decidedly in the improved qualifications of generations of graduates yet to come, and, since old Homer sung, nobody but an occasional unmitigated scoffer has raised the shadow of a doubt as to the supreme importance of the highest possible development of the healing art.

By this act, therefore, Mr. Vanderbilt has most pointedly shown his title to the gratitude of his fellow-citizens. We are not of those who ignore the evils that are thought to go hand in hand with the amassing of huge fortunes by individuals—we believe them to be real and not imaginary; but it is a great mitigation of those evils for a man of vast wealth to give a tithe of his possessions to the cause of suffering humanity. It is one of those touches of nature that make the whole world kin. The humblest beneficiary of medical care—and they are to be counted every year by the million—may now profit directly, in the heightened quality of his dole, by this one act of a rich man. Surely such a deed should go far to reconcile the poor to a splendor they must look upon but may not share. Let us hope that, so far as material benefactions are concerned, medicine has at last entered upon an era of good fortune; and, indeed, there seems to be good ground for the hope when, within the space of a single year, Sir Erasmus Wilson's munificent bequest to the Royal College of Surgeons, Mr. Carnegie's gift to the Bellevue Hospital Medical College, and now this princely endowment of the College of Physicians and Surgeons by Mr. Vanderbilt, have all been chronicled.

We will not speculate as to whether or not the specific direction taken by Mr. Vanderbilt's generosity was the result of a deliberate judgment on his own part, or whether it is to the intercession of some member of its own faculty that the College of Physicians and Surgeons is indebted for its good fortune; it is enough for us to know that the gift has been wisely bestowed. The College of Physicians and Surgeons is

seventy-seven years old, and its career during those seventy-seven years has been that of an institution honestly striving to equip its pupils with the best medical education that the condition of our country would allow of. That its success in this attempt has not been below what circumstances would reasonably lead one to expect is amply attested by the status of its graduates. But in the struggle it has yearly seemed to be more and more handicapped by its comparative remoteness from any hospital. Now, however, this clog is to be cast off—we learn that the college has acquired the title to a large tract of land in the immediate vicinity of the Roosevelt Hospital (of which its president is *ex officio* a member of the board of governors), and we have no doubt that suitable buildings will be put up on it at once. This means, undoubtedly, a close alliance between the two institutions, if not their virtual amalgamation, with the result of adding notably to the resources of the college in the way of clinical teaching.

When a man—or, for that matter, a corporation—falls heir to a snug sum, there is commonly no lack of kind friends to offer advice as to the ways in which the money may be used to advantage. Granting that their recipient should usually feel grateful for such attentions, we are convinced that in this instance the fortunate institution is abundantly capable of shaping its own ends, and we look forward with confidence to its making the best possible [use of its new-found wealth. While we heartily congratulate the college, we can not overlook the higher significance of the occasion of that congratulation which is so admirably set forth by Dr. Flint in the foot-note to his paper published in this issue of the journal.

FACTS AND THEIR APPRECIATION.

IN Dr. Flint's admirable presentation of the points connected with the doctrine of the parasitic origin of cholera, which will be found in this issue of the journal, a suggestion is thrown out that seems to us to embody an idea which ought to be more borne in mind than it has been of late years. "In order to discuss and decide upon these questions," he says, "it is by no means essential that we shall have practically verified the microscopical examinations on which rests the evidence of the parasitic doctrine. In courts of law, the judges, advocates, and juries are not themselves observers of facts involved in cases on trial. They deal with facts as established by testimony. So it must be with scientific facts. They are to be canvassed, and either accepted or rejected on the statements of competent witnesses." Further on, he adds: "When in London during the past summer, I visited the Biological Department of the Health Exhibition at Kensington Gardens, and I there saw a specimen of the so-called cholera bacillus. It had been prepared by Koch himself. The demonstration was interesting, but it would be absurd to claim therefrom any advantage in judging of the merits of the doctrine which assumes that this organism is the essential cause of epidemic cholera."

And yet, we venture to say, there are very few members of the profession who would read with deference a statement

on such a subject, unless it came either from a skilled observer or from a man who had attained to the commanding position occupied by the gentleman whose words we have quoted. This is all wrong. The tendency has been too great of late years, doubtless from the backward swing of the pendulum away from the old times of authority, to subordinate the reasoning powers to the mere observation of physical processes. It is equivalent to saying—as the vulgar are very much given to saying—that nobody is qualified to criticise a picture unless he can paint a better one himself. We are far from underrating the great debt that modern medicine owes to pure observation; indeed, we are quite in accord with the feeling that, just at this juncture, competent observation is the chief thing needed to advance our art. But we may be allowed to add that it is not the only thing needed. Blocks of stone may be carved with the greatest nicety, but the real work of constructing an edifice is done by him whose hands are entirely unused to the actual play of tools. The parallel must be reversed, it is true, for in material building it is the architect's conception that must precede the mechanical work, while in science the preparation of the materials has to go before the constructive process; but the deduction remains obvious, that the greatest service is rendered not by him who digs out facts, but by him who welds them together. We must, therefore, deprecate the infatuation which honors only the discoverer, and gives the cold shoulder to the critic.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 21, 1884:

DISEASES.	Week ending Oct. 14.		Week ending Oct. 21.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	42	13	50	13
Scarlet Fever.....	39	5	25	5
Cerebro-spinal meningitis....	2	2	6	4
Measles.....	6	6	36	4
Diphtheria.....	45	29	43	30
Small-pox.....	1	0	0	0

The New York Obstetrical Society.—At the annual meeting, held on Tuesday evening, the 21st inst., officers were elected for the ensuing year as follow: President, Dr. William M. Polk; vice-presidents, Dr. Henry F. Walker and Dr. Alexander S. Clarke; secretary, Dr. Frank P. Foster; corresponding secretary, Dr. Emil Noeggerath; treasurer, Dr. Edward L. Partridge; new members of the committee on admissions, Dr. James B. Hunter, Dr. Horace T. Hanks, and Dr. Robert Watts. The by-laws were so amended as to do away with the June meeting hereafter.

The Medical Department of the University of Pennsylvania.—For some weeks past there have been rumors of an intention on the part of the governing board of the university to extend a call to Professor William Osler, of McGill University, Montreal, to take the chair of clinical medicine; and it is now definitely announced that Dr. Osler has been called to the chair. We are convinced that the choice will prove to have been an admirable one.

The Death of Professor H. von Zeissl, the distinguished syphilidologist, is announced as having taken place at Vienna on the 23d of September, at the age of sixty-seven years.

Mr. Lawson Tait's Operations at Bellevue Hospital.—We are glad to be able to state that the two patients from whom Mr. Tait lately removed the uterine appendages, on the occasion of his making the clinical remarks which we published last week, have both recovered, making a happy issue out of the doubt that Mr. Tait felt as to the safety of doing the operation in a large general hospital and in the presence of a great number of spectators.

The German Universities.—The "Lancet" learns that Professor H. Kronecker, of Berlin, has accepted a nomination to the chair of physiology at Berne, succeeding Professor Grützner, who goes to Tübingen, and that Professor Hermann, of Zürich is to take the same chair at Königsberg, succeeding Professor von Wittich.

The Contagious Pleuro-pneumonia of Cattle now prevailing in several of the western States is said to have been traced to a herd of cattle sent west from Baltimore. All the affected cattle west of Ohio are stated to be thoroughbred Jerseys.

The Land lately purchased by the College of Physicians and Surgeons comprises the western portion of the block bounded by Ninth and Tenth Avenues and Fifty-ninth and Sixtieth Streets, directly opposite the grounds of the Roosevelt Hospital, which include the whole of the block below. It is understood that the new college building will cover a space measuring two hundred by three hundred feet.

The New York Hospital Training School for Nurses.—We learn that Miss Lizzie Johnson, a graduate of the school, has been appointed superintendent of the training school for nurses of the Buffalo City Hospital; also that Miss Emma L. Warr, another graduate of the school, has lately gone to St. Louis, to establish a training school in connection with the St. Louis City Hospital.

The Relative Value of Facts and Opinions, as estimated by one of our London contemporaries, may be learned from the following passage, which we find in its review of the second volume of Dr. Morell Mackenzie's work on "Diseases of the Throat and Nose": "That one practitioner in Illinois has twice treated nasal polypus with perchloride of iron, while another has been no less successful in Baltimore with chromic acid, strikes us as a form of difference which may fitly be compared to the immortal contention of Tweedledum and Tweedledee, and certainly forms a sorry substitute for the deliberate opinions of Dr. Morell Mackenzie."

Changes in the Paris Hospitals.—The "Union médicale" learns that, in consequence of the death of M. Moreau, M. Jules Falret, physician to the Bicêtre, has been transferred to the Salpêtrière, and that M. Charpentier, adjunct physician to the Salpêtrière, has been appointed physician to the Bicêtre.

Cremation in Italy.—It is announced that the Italian Government has ordered the building of a crematory, on the Gordini-Guzzi system, for the cholera lazaretto at Varignano.

Precautions against the Introduction of Diseased Cattle into Kansas.—A proclamation by the Governor of Kansas forbids the importation of cattle from Kentucky, Iowa, Nebraska, or Missouri until they have been submitted to a detention of sixty days at the point of introduction, and have been certified by the State veterinarian to be free from disease. The proclamation also forbids the introduction of Jersey cattle.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 12, 1884, to October 18, 1884:*

NORRIS, BASIL, Lieutenant-Colonel and Surgeon. Relieved from duty as Attending Surgeon, Washington, D. C., and ordered for duty as Medical Director, Division of the Pacific and Department of California, relieving Surgeon E. I. Bailly. Colonel Bailly, on being relieved, will assume the duties of Attendant Surgeon at San Francisco, Cal. S. O. 242, A. G. O., October 15, 1884.

SPENCER, WILLIAM C., Major and Surgeon. From Department of Dakota to Department of the East. S. O. 242, A. G. O., October 15, 1884.

GODDARD, CHARLES E., Major and Surgeon. To be relieved from duty at Jefferson Barracks, Missouri, and to report for duty in Department of Dakota. S. O. 242, A. G. O., October 15, 1884.

McLELLAN, ELY, Major and Surgeon. From Department of the East to duty at Cavalry Depot, Jefferson Barracks, Missouri. S. O. 242, A. G. O., October 15, 1884.

McKEE, JAMES C., Major and Surgeon. Granted leave of absence for one month, with permission to apply at Division Headquarters for one month's extension. Par. 1, S. O. 149, Department of the Columbia, October 3, 1884.

WOLVERTON, W. D., Major and Surgeon. Granted one month's leave of absence, to take effect when his services can be spared by his post commander. Par. 4, S. O. 211, Department of the East, October 16, 1884.

HAYARD, VALERY, Captain and Assistant Surgeon. Assigned to temporary duty at Fort Schuyler, New York Harbor, N. Y. Par. 2, S. O. 211, Department of the East, October 16, 1884.

PORTER, J. Y., Captain and Assistant Surgeon. Granted leave of absence for one month on surgeon's certificate of disability, with permission to leave the limits of the department. Par. 3, S. O. 138, Headquarters Department of Texas, October 9, 1884. (Confirms telegraphic order of same date.)

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending October 18, 1884:*

BRUSH, GEORGE R., Surgeon. Assigned to temporary duty at the Naval Laboratory, October 11, 1884.

BURBANK, CHARLES H., Medical Inspector. Detached from the Brooklyn and placed on waiting orders, October 15, 1884.

CLARK, JOHN H., Surgeon. Detached from the Lackawanna and detailed as Fleet Surgeon of the Pacific Station, October 17, 1884.

COOKE, GEORGE H., Surgeon. Ordered to the Lackawanna, October 17, 1884.

EDGAR, JOHN M., Passed Assistant Surgeon. Ordered to the Receiving Ship Franklin, October 11, 1884.

HUPSON, A., Medical Inspector. Detached from the Lancaster and placed on waiting orders, October 14, 1884.

HUGG, JOSEPH, Surgeon. Placed on waiting orders, October 13, 1884.

LOVERING, P. A., Passed Assistant Surgeon. Detached from the Lackawanna and placed on waiting orders, October 17, 1884.

MARSTELLER, E. H., Passed Assistant Surgeon. Detached from the Monongahela and ordered to the Lackawanna, October 17, 1884.

MARTIN, WILLIAM, Assistant Surgeon. Detached from the Pas-saic and placed on waiting orders, October 14, 1884.

MARTIN, H. M., Passed Assistant Surgeon. Detached from the Brooklyn and placed on waiting orders.

Society Meetings for the Coming Week:

MONDAY, October 27th: Medical Society of the County of New York (annual); New York Academy of Sciences (section in Physics, Astronomy, and Mathematics); Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement.

TUESDAY, October 28th: American Academy of Medicine (Baltimore—first day); New York Surgical Society; Medical Societies of the Counties of Putnam, Queens, and Rockland, N. Y.; New York Dermatological Society; Jersey City Pathological Society (private); Boston Society of Medical Sciences (private).

WEDNESDAY, October 29th: American Academy of Medicine (second day); New York Pathological Society; American Microscopical Society of the City of New York; Auburn, N. Y., City Medical Association; Medical Society of the County of Gloucester, N. J.; Berkshire, Mass., District Medical Society (Pittsfield); Middlesex, Mass., North District Medical Society (Lowell); Worcester, Mass., Association for Medical Improvement (private); Cumberland County, Me., Medical Society.

THURSDAY, October 30th: Massachusetts Medical Benevolent Society (annual—Boston).

SATURDAY, November 1st: Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of October 16, 1884.

The President, FORDYCE BARKER, M. D., LL. D., in the chair.

A Bronze Bust of the Late Dr. J. Marion Sims.—A copy of a marble bust by Du Bois, of Paris, was presented to the Academy by Dr. H. MARION-SIMS.

THE PRESIDENT, in behalf of the Academy, accepted the generous and beautiful gift, made some eulogistic remarks upon the late Dr. Sims, and spoke of the bust as almost a speaking likeness.

DR. WHITE offered resolutions of thanks to the donor, which were unanimously adopted.

A Memoir of the Late Dr. Willard Parker was read by Dr. WILLIAM H. DRAPER. He pictured Dr. Parker as a man of great intelligence, with an honest mind and indomitable will, a lover of freedom, and a believer in the dignity of labor. As a practitioner of medicine, while a surgeon he was also what the English would call "an all-round man." He was broad in his views, had unbounded faith in the possibilities of the healing art, and was enthusiastic as a teacher. He was not what would be called a learned man, but he was what many learned men never became—a wise man. He was always self-possessed; no emergency could disconcert him, no disease appall him. He was a keen and comprehensive observer, and always seemed to see what was best worth seeing. He was a physician of the Hippocratic type: a physician of experience and common sense. It was in his character as a public teacher that Dr. Parker exerted his widest influence; there was something about his enthusiasm which was contagious. He took a special interest in hygiene and public health. He believed that disease was the direct and evident consequence of ignorance or defiance of the laws of health, and that the dissemination of knowledge regarding those laws was the best means for preventing the ravages of

disease. Dr. Parker's name as a surgeon was connected specially with cystotomy for the relief of cystitis, and with the operation for perityphlitic abscess; but surgery for him was rather a part of the equipment of the general practitioner.

Dr. Parker took a deep interest in the question of intemperance in the use of alcoholic stimulants. He recognized in this one of the chief causes of physical degeneracy as well as of poverty and crime. He abstained from the use of liquors himself, believing that he could maintain the highest degree of health without them.

The Therapeutical Effects of the Internal Administration of Hot Water in the Treatment of Nervous Diseases.
—Dr. AMBROSE L. RANNEY read a paper with this title. [See pages 426 and 456.]

Dr. E. C. SEGUIN said he had had but little experience in the use of hot water except in a limited class of cases; he had not used it in cases of destructive nervous disease. It seemed to him there were some points in the paper which were open to discussion. The first was the quality of the agent used. The author had specified the agents which produced heat as warm, hot, very hot, and the actual cautery. Dr. Seguin thought a temperature of 110° to 150° F. could hardly be considered hot, especially as the temperature of the water diminished while it was being swallowed. In the second place, as to the cases brought forward by Dr. Ranney, a large number of them seemed to be cases of neurasthenia, cerebral hyperæmia and anæmia, and functional disturbances of a similar kind. These cases, it seemed to him, constituted one of the most doubtful classes in disease, for many of them were nothing more than cases of mal-assimilation, and here Dr. Ranney employed a combined treatment, including a diet which would of itself tend to correct disturbances of digestion and mal-assimilation. Again, he asked if it was not possible that some of the good effects were due to the water and not to the element of heat. It had been observed that in this class of cases there was often a lack of desire for water—hydroadipsia, as it had been termed by Dr. McElroy—and the patients were often benefited by drinking a larger amount of simple water than their natural thirst prompted them to take. The author had been guided largely in his treatment by the condition of the urine, which was another fact which went to support Dr. Seguin's view. With respect to the use of hot water in the treatment of organic nervous affections he could say nothing, as he had had no experience. As to the theory of the mode of action by reflex influence, he had no doubt there might be some foundation for this, but if a share of the good effect was to be attributed to the washing out of effete material from the system by the fluid taken, and he believed this share to be considerable, the share which remained for the effect of reflex action by the heat in the stomach could not be very great.

He wished to say a word in defense of cold water. He could see no objection to ice-water, and on the same principle on which he questioned the influence of the degree of heat mentioned, namely, that the fluid did not reach the stomach of the same temperature which it possessed when taken into the mouth.

Dr. R. W. AMIDON had for some time used hot water in the treatment of nervous phenomena connected with dyspepsia or the gouty or rheumatic diathesis. He agreed with the last speaker that the action of the hot water as a derivative or counter-irritant was extremely doubtful. He did not believe that when it reached the stomach it was sufficiently hot to produce a counter-irritant effect. He understood the author to say that the beneficial effects of the hot water were obtained only after six months, but his own experience taught him that counter-irritants acted much sooner than that. He believed the

hot water acted more as a diluent; that it increased destructive metamorphosis and the powers of assimilation.

Dr. L. PUTZEL thought the theory concerning the action of hot water taken into the stomach, as advanced by the author of the paper, proved too much, for he had said that the agent had acted beneficially both in cases of cerebral hyperæmia and in those of cerebral anæmia. He did not think it could act beneficially in opposite conditions. He would lay some stress upon the point made by Dr. Amidon, that an agent which acted by its irritant effects should produce its results quickly. He would suppose that the best results from the use of hot water would be obtained in the commencement of the treatment, as afterward the stomach would become habituated to the irritation.

Dr. W. R. BIRDSALL believed there was a good deal of efficacy in hot water, as well as in cold water, when used as a therapeutical agent. He was not prepared to deny the influence which it had been stated heat played in this mode of treatment. But what he had been most anxious to hear was statistics of a clear character, which would enable us to judge of the effects of hot water, particularly in the class of cases which were strictly disorders of the nervous system, such as locomotor ataxia. But, unfortunately, the patients whose cases the author had related had been submitted to a combination of treatment, and not to that by hot water alone, and we were therefore unable to tell what part had been played by this agent in the production of the beneficial results. In the cases of functional disturbance of the nervous system it would be difficult to say how much of the good result was to be attributed to the heat and how much to the diluent properties of the agent. With regard to whether the water reached the stomach in a hot state, he thought it might begin to produce the effects due to its heat the moment it came in contact with the mucous membrane in its passage down to the stomach. His impression was that it was not the influence of the heat upon the vaso-motor system alone which caused the results; it might also have produced some influence upon another system of nerves.

Dr. C. L. DANA had used hot water in cases of nervous disorder associated with gastric disturbances, particularly in hysterical women, but he had not been impressed with its efficacy. The want of favorable results, however, might possibly have been due to lack of carrying out the treatment as persistently as the author recommended. He believed that the paper would result in benefit in suggesting a mode of treatment for a class of cases which usually resisted almost all kinds of treatment, and, as Dr. Wilks had years ago pointed out, those agents which were not directed immediately to the nervous system were more likely to prove efficacious in the treatment of this class of disorders.

Dr. J. L. CORNING had obtained good results from the use of hot water in cases of so-called neurasthenia with concomitant gastric disorders. He had attributed the good effect to the influence produced upon the mucous membrane of the stomach by the hot water. He had obtained good results in from six weeks to two months.

Dr. JOHN SCOTT, of San Francisco (present by invitation), had employed hot water in checking emesis in general, and that after the administration of ether in particular. He had also during the past thirty years given water in another form, in the form of a milk diet, with great benefit in many disorders.

Dr. RANNEY, closing the discussion, said that any one who would take hot water as he had recommended would be convinced after drinking it that it reached the stomach in more than a warm state. Hot water could not lose much of its heat before it reached the stomach. It had been suggested by some of the speakers that the beneficial effects produced by the hot

water were due to its diluent qualities, but he had obtained results with four goblets of hot water a day which could not have been obtained by as many gallons of water in its ordinary state. He had been misunderstood to say that the effects were produced only after the lapse of six months. What he did say was that in some cases it took from five to six weeks to get marked effects, and in some six months to produce the full effects. The theory which he had suggested concerning the action of the agent seemed to have been the chief basis of the discussion and adverse criticism. He had advanced the theory simply as being to him the most plausible, but it might be entirely incorrect, yet the facts as to the results of treatment by the swallowing of hot water existed. As to Dr. Putzel's criticism, that benefit could not be produced in opposite conditions, in both cerebral hyperæmia and cerebral anæmia, he would say the agent had a tendency to restore the parts to their normal condition, and in so doing would tend to relieve any abnormal condition which might exist in the brain. One man who drank whisky would become bloated and fat, while another taking the same agent would lose flesh and become thin. It had been doubted whether his cases proved anything, as different agents were employed in the treatment at the same time. But the other measures had failed to produce any benefit until combined with the use of hot water. It followed, therefore, either that the hot water alone had produced the beneficial result, or that hot water combined with other remedies had done so.

Dr. T. H. BURCHARD asked Dr. Ranney whether he had observed any permanent disturbance of the digestive system produced by the hot water when used for some time, and also whether he had observed that it caused a tendency to internal hæmorrhages. He had seen many patients at Saratoga Springs who had been treated by this method, and, after five or six months, had experienced disturbance of digestion, lost flesh, and become greatly reduced in health. Others had shown a tendency to gastric and intestinal hæmorrhage.

Dr. RANNEY replied that he had never known intestinal hæmorrhage to occur in a patient to whom he had administered hot water, and he had treated a great many patients in this manner; nor had he known it to produce permanent disorder of the digestive powers. He had known patients to lose weight rapidly, but it was due to the restricted diet which had been purposely recommended, and they quickly regained their weight on returning to a general diet.

A New Local Anæsthetic.—Dr. C. R. AGNEW made some remarks upon hydrochlorate of cocaine as an anæsthetic when applied to the conjunctiva. Since attention had been called to the subject by a letter published in the "Medical Record" for October 11th, he had employed the agent in a number of cases in which he had performed operations upon the eye, and both he and the observers had been satisfied and greatly astonished at the results. He felt that nothing of greater value had been given to surgery since the discovery of anæsthesia with ether and chloroform. He distinctly disclaimed any priority in its use in this city. The action of the agent was demonstrated upon two gentlemen present at the meeting. It had not been positively determined whether it was capable of producing local anæsthesia in wounds of the skin.

Dr. BURCHARD said it had produced anæsthesia in the finger, the seat of a felon, so that he had been enabled to open it without pain to the patient.

Dr. BIRDSALL had been in the habit the past two years of employing coca to produce a benumbing effect upon the mucous membrane of the air-passages.

The PRESIDENT referred to the effects of the fluid extract in clearing the voice.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Meeting of October 20, 1884.

The President, Dr. WILLIAM DETMOLD, in the chair.

The Parasitic Doctrine of Epidemic Cholera.—Dr. AUGUST FLINT read a paper with this title. [See page 451.]

After the reading of the paper, the PRESIDENT said he had no doubt that he expressed the feelings of all those present in extending thanks to Dr. Flint for the very interesting and valuable paper which they had had the pleasure of listening to. While he did not feel able to open the discussion on the subject, he would venture to say that, in his mind, there was little doubt that there existed a certain relationship between summer diarrhoea and Asiatic cholera. Affections of all the mucous membranes, when they occurred repeatedly under favoring circumstances, were liable to become contagious. Thus, take simple catarrhal ophthalmia, which here was a simple local disease; in a locality where the climate and other circumstances favored its development, as in Egypt, it became contagious. In the country mentioned (Egypt), where the eyes were much exposed to dust and to the reflection of the sun's rays from the sand, ophthalmia, which probably was at first but a simple catarrhal affection, became contagious, and had been carried to other parts of the world, especially during the Napoleonic wars. He supposed that cholera infantum stood in a similar relation to Asiatic cholera; at any rate, it would be interesting to ascertain whether the dejections in cholera infantum contained a microscopic organism resembling or analogous to that found in Asiatic cholera. That the diarrhoeas here which proved so fatal among children should, in a climate like that of India, become contagious, like Asiatic cholera, would not be at all wonderful.

He then said that papers upon the same subject had been promised by Dr. Janeway and by Dr. Leale, to be read at an approaching meeting of the association, and at that time perhaps the members would be better prepared to take up the discussion.

Dr. E. G. JANEWAY said the arguments for and against the parasitic theory regarding Asiatic cholera had been so thoroughly considered by the author of the paper that scarcely any ground was left for discussion. He would allude a little more particularly to the means taken for the prevention of cholera in this city in 1866-'67. Having been an interne in the workhouse on Blackwell's Island the year previously, he was acquainted with the conditions which favored the development of cholera there, and informed the sanitary officer, who had them corrected. It was the habit to use pails for the dejections of the inmates, which were allowed to stand in the room until the next day, when they were carried to the river and there emptied. There were at the same time persons in the workhouse who had returned from the war and were suffering from scurvy, and acid was given with their food as a remedy against that disease—the remedy not then being supposed to have any influence upon the cholera. As soon as the sanitary officers had been informed of the condition of things, the Chairman of the Committee on Inspection ordered that the pails be left out of the rooms, that disinfectants be used, and that every person, as soon as he was taken sick with cholera, should be transported to the hospital and isolated; and thus it was not long before cholera entirely disappeared from the institution. Dr. Janeway thought there was some danger of the public getting the impression that the only, or nearly the only, source of spread of cholera was through the drinking-water, or the food which became contaminated through the water. While this might be one of the principal modes of spreading the disease, it was not the only one, and could not have acted during the existence of the cholera

in the workhouse on Blackwell's Island in the two years mentioned. He also believed that, while heat might be an efficient way of killing the germ of the disease, it could not be applied in the way of desiccation so as effectually to stop the spread of an epidemic in a large city, and it was not this means by which the Sanitary Board of New York was enabled to stamp out the cholera when it was prevalent here in 1866-'67. Probably the only way in which heat could be used, to be of any practical benefit, would be to burn all the clothing and soiled articles which had been worn by persons sick with cholera. The same principles applied here which applied in the prevention of the spread of small-pox, typhus fever, and other contagious diseases. He recalled an example in which a pair of slippers must have been the only origin of an outbreak of small-pox at a place fifty miles distant from where the owner had been sick with the disease. The small articles, therefore, would have to be looked after as well as the larger ones if we wished to effectually prevent the spread of an epidemic of cholera, small-pox, etc. Again, there was a tendency on the part of some physicians to sympathize with the relatives, and, when a patient was sick with a disease of a suspicious kind, to give him the benefit of the doubt, and not regard it as small-pox, typhus fever, scarlet fever, or cholera, until time had proved it certainly to be such; and by taking this action they perhaps unintentionally permitted the spread of a dangerous contagion. As an officer of the Board of Health, he had learned of more than one instance in which a physician had regarded a dangerous contagious disease as an innocent or mild one in the beginning, and had thus been the indirect cause of the death of a number of persons. Each individual physician should hold himself responsible for every case of disease of a suspicious character which came under his observation, and thus assist in effectually establishing a quarantine against cholera, small-pox, etc. The city should pay the patient for any loss he might incur by permitting the sanitary officers to burn soiled clothing. So far as the germ-theory of cholera was concerned, Dr. Janeway's convictions were in accord with those of the author of the paper.

The PRESIDENT said that when the cholera first made its appearance in New York in 1866 the orders given for the purpose of stamping it out were, to cast the dejections into the water-closet and to burn the clothing. The first measure—to cast the dejections into the water-closet—seemed to him to be an ineffectual way to prevent the spread of the disease; it was more likely, by going into the sewers, to result in a fresh outbreak at distant points. He therefore suggested that the dejections first be disinfected. With regard to the second measure—that all the clothing and bedding be burned—it also seemed hard that a poor woman should be compelled, perhaps, to burn her last quilt for the sake of protecting a wealthy city against the possibility of the spread of the cholera. The city was therefore induced to pay for all soiled clothes or to substitute new ones, and the result was that the family, not losing anything by the transaction, had no object in concealing soiled articles, brought them forward, and, perhaps, even some that belonged to their neighbors. These two measures he believed to have been of the greatest importance in stamping out the cholera during the epidemic in question.

Dr. C. A. LEALE wished to bear testimony, with Dr. Flint, to the great service rendered the city by the Metropolitan Board of Health in 1866-'67. At that time he was attending cases of cholera at several different places, and among others one at West Fifty-second Street. Here eighteen cases of Asiatic cholera came under his immediate observation, with five deaths. He struggled against the disease, laboring night and day, the usual means of fumigation and disinfection then recommended being resorted to without avail, and at last he laid the matter before

the Board of Health. The late Dr. Dalton then came over with all of his assistants and completely enveloped the house in chlorine-gas, and not a single case of cholera occurred in the neighborhood subsequently.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of September 17, 1884.

(Concluded from page 446.)

Dupuytren's Contraction of the Fingers.—Dr. W. MURPHY JANEWAY read the following report of a case that had occurred in the Polyclinic service of Dr. C. K. Mills:

Dr. W. W. Keen, in one of the most valuable papers on "Dupuytren's Contraction" * published in recent years, states that he was able to find, exclusive of his own cases, twenty-six

FIG. 1.

in number, only ninety-five other recorded cases. It has been, therefore, thought worth while to put the following additional

FIG. 2.

case briefly on record. The history points to a rheumatic or rheumatico-gouty origin of the affection.

H. B., aged seventy, married, born in Ireland, had one sister

* "The *Ætiology and Pathology of Dupuytren's Contraction of the Fingers.*" A paper read before the Philadelphia County Medical Society. By W. W. Keen, M. D. "Philadelphia Medical Times," March 11, 1882.

with a rheumatic history. His father died of pleurisy, and he did not know the cause of his mother's death, or any details of the health history of either parent. He denied syphilis positively, and never injured his hands in any way. He has kept a trimming-store for twenty years, and before that time was in the grocery business. He was in California thirty-five years ago, being one of the "forty-niners." He slept in a tent, and mined for gold for twenty months, but apparently did not suffer, or at least not immediately, from the exposure. For fifteen years he has suffered with rheumatic or rheumatico-gouty pains.

Twelve years ago the little finger of the left hand began to curve inward; contraction soon followed in the ring, and later in the middle finger. The little finger of the right hand also gradually contracted.

When he presented himself at the Polyclinic the joints of his hands and fingers were found to be enlarged. The little finger of the right was strongly flexed; but the trouble was much more marked and extensive in the left hand, the little and ring fingers being drawn in so as to almost touch the palm of the hand, the second finger also being much contracted. (See Fig. 1.*). Ridges were found running to these fingers across the palm. The general strength of both upper extremities was about the same. He had never had any special treatment for the contractions.

Subcutaneous incisions were made into the palmar fascia and its cord-like prolongations by Dr. John B. Roberts. In all, eight incisions were made at a single sitting. The hand was straightened, and kept in a digital splint for six weeks, manipulations also being used. The splint was then used only at nights, and galvanism was applied in the form of the continuous current through the hand, and the current interrupted to the interossei and other muscles. The hand is now capable of being straightened, as shown in Fig. 2, and he also has much improved use of it in flexion and extension.

Dr. MILLS said that many surgeons referred all such cases to traumatism. The chief interest in them was the pathology and causation. He believed that most cases of true Dupuytren's contraction were due to rheumatism or rheumatic gout. Hysterical contraction sometimes resembled it, but continuous nerve pressure on the median nerve would relax this form, although it would subsequently return. Some of the cases called atelectosis also resembled it. Here there were no ridges across the palm, and the contractions could be readily overcome temporarily.

Dr. JOHN B. ROBERTS thought the case showed facts in opposition to the theory of traumatism as a cause, for the man was now under treatment for chronic arthritis of the fingers. It was a pity that the name Dupuytren's had been given to this form of contraction, for, if we called it contraction of the palmar fascia, we at once separated it from the contractions of tendons. A proof of its rheumatic origin was the frequency of its occurrence in those who did no manual labor.

Dr. ANGVEY said the history of the case showed no traumatism. The man had been a shop-keeper, and had the trouble ten or twelve years before consulting a physician. Rheumatism and gout were concerned in the aetiology.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Meeting of October 2, 1884.

The President, Dr. R. A. CLEMMANN, in the chair.

Submucous and Interstitia Fibro-Cystic Tumor of the Uterus without Hemorrhage.—Dr. B. F. BAER exhibited

* The cuts illustrating this case were kindly furnished by Messrs. P. Blakiston, Son & Co.

specimens from a case of this sort. Mrs. H., aged thirty-six years, had had two children, the youngest being twelve years of age. Four years ago she suffered from severe metrorrhagia which was caused by a submucous and interstitial fibroma of the uterus. This was removed, and, after passing through a severe attack of pelvic inflammation, she recovered. After the removal of the growth her catamenial periods became regular in time and quantity and she remained well until about one year ago, when she began to have a very fetid watery discharge in the intermenstrual periods, with sacral pain and uterine tenesmus. On July 17th, her physician, Dr. R. Armstrong, of Lock Haven, requested Dr. Baer to see her with him, when examination showed the cervix to be of twice its normal size, with swollen and gaping lips, making the os and cervical canal quite patulous. The body of the uterus was as large as at the third month of gestation, but it was not symmetrically developed, being larger on the left side than on the right. The left broad ligament was indurated and seemed to be the seat of an old inflammatory process. Pain had been present in this region since the operation. The sound met with an obstruction at the internal os, and was deflected to the right, passing to a depth of nearly four inches. It could be made to pass around a mass of some kind in the cavity of the uterus, giving an indistinct sensation of the presence of an abnormal growth. Dr. Baer expressed the opinion that, although there had been no hemorrhage, there was a submucous or polypoid fibroma present, and advised its removal. Seven tents were introduced, and twenty-four hours afterward ether was administered, when, with the assistance of Dr. Armstrong, Dr. Walls, and Dr. Ball, he proceeded to remove the tents and explore the uterine cavity. On passing his finger within the internal os, he detected a smooth, oval-shaped mass of tissue resembling in consistence an inverted uterus enlarged to about double its normal size. He carried his finger up with some difficulty, and found the base or attachment of the tumor to be located at the fundus of the uterus, where it was narrowed somewhat, forming a sort of pedicle. The tumor felt rather soft for a fibroma, and this, together with its shape, caused him to suspect inversion of the uterus, and, when he remembered that the organ was sometimes inverted by the operation for the removal of an interstitial fibroid which required great traction, as was necessary in this case four years previously, he became much more anxious to investigate fully before attempting to remove the mass. By very careful and thorough bimanual manipulation he convinced himself that the uterus was not inverted, and that there was no indentation anywhere on its surface. He therefore felt warranted in adjusting the wire of an écraseur around its attachment, and proceeded to tighten it, but the traction and manipulation which were necessary in placing the noose broke the surface of the tumor and exposed a peculiar-looking membrane which resembled the peritonæum. He was alarmed at this, fearing that he had really to deal with a partially inverted womb, and that the smooth membranous structure was the peritonæum. He removed the écraseur, the wire of which had broken, and then passed one finger into the bladder and another into the rectum for the purpose of determining more certainly the condition of the peritoneal surface of the uterus. Now, while an assistant made traction on the supposed tumor, he was enabled to satisfy himself fully that the organ was not inverted. He then removed the tumor by enucleation. As would be seen in the specimen which he presented, there are a number of cysts. These cysts contained the semi-opaque coagulable fluid usually found in fibro-cysts, and gave to the tumor its softness, which, together with its shape and the appearance of the cyst-walls when its surface was broken, made it resemble an inverted uterus. The patient made a good recovery.

The case was very unusual for the reason that, although the uterine cavity was distended by a large submucous tumor which was becoming polypoid, not the slightest hæmorrhage resulted. He did not remember to have met with a similar case. He had, however, met with cases of small polypi where there was no hæmorrhage. Two, indeed, were discovered after the menopause had been fully established, and were worthy of record because of the reflex symptoms which they seemed to induce.

Uterine Polypus without Hæmorrhage; Symptoms of Pregnancy.—One of the cases Dr. Baer alluded to was that of Mrs. C., forty-six years of age, who had been married twenty years, but had never been pregnant. The menopause had occurred one year previous to the date at which he saw her. Soon after the cessation of the catamenia her abdomen began to enlarge and she thought she was pregnant. Various irregular reflex symptoms of pregnancy developed, and she became so convinced that she engaged the services of an accoucheur and nurse, and went into labor in due time. Her physician, Dr. John H. Musser, was unable to discover the least physical sign of gestation, nor anything else which should give rise to the almost perfect labor-like pains which she seemed to have at irregular intervals. He informed her that she was not pregnant. She became indignant, and asked him to call another physician to confirm what he said. He consented, and requested Dr. Baer to see the patient. Dr. Baer excluded pregnancy, but found in the cervical canal a fibrous polypus not larger than an ordinary marble. This he at once removed, and the pains and other signs of gestation immediately subsided.

This was one of those cases of spurious pregnancy which we sometimes saw developed in a sterile woman about the period of the menopause. The desire for offspring was strong. The cessation of the menses started the delusion, and it was kept in existence and made to grow by being constantly fed by a morbidly susceptible nervous system. But there was a local irritation here to account for the reflex symptoms of gestation, as he believed there was in the majority of these rare and interesting cases. It was now three years since this patient was under treatment, and there had been no return of the reflex disturbance.

Uterine Polypus without Hæmorrhage; Severe Reflex Head Symptoms.—The other case to which he wished to refer had occurred in the practice of his friend, Dr. B. Trautman, who kindly asked him to see the patient with him. Mrs. K., aged fifty-two years, had had two children, the youngest being twenty-five years of age. The menopause had occurred four years previously, and she did not complain of the slightest local symptom of uterine disease, but the flushings and other nervous manifestations which often attend this period had not yet subsided. The disturbances, however, which concerned her most, and for which she consulted the doctor, were a pain and pressure of a very aggravated form on the top of the head. Many remedies had been prescribed for the relief of this, but with only temporary benefit. A uterine examination was made, and a polypus resembling in size a small walnut discovered in the canal of the cervix. This was removed some months ago, and he believed the patient had been relieved of the headache and other reflex symptoms which seemed to result from its presence.

The influence which these small growths had on the nervous system was something remarkable, but the absence of hæmorrhage, especially in the first case, was more notable when we recalled the size and location of the tumor, and remembered that death had resulted from the hæmorrhage caused by polypi not larger than a pea, as recorded by Locock, Klob, Courty, and others. He had no doubt some of the gentlemen could recall cases, as he could, where death would doubtless have resulted

from the hæmorrhage produced by a small polypus, had not the cause of it been removed. The following is an illustrative case:

Uterine Polypus attended with great Hæmorrhage.—Mrs. P. consulted him September 20, 1883. She was thirty years of age, and had been married eight years, but had been sterile. Two years ago she began to suffer from menorrhagia with uterine tenesmus. Soon after, she lost blood at irregular intervals, and in large quantities; during the past year she had not often been free from metrorrhagia or a profuse and offensive leucorrhœa. The hæmorrhage would sometimes last a whole month continuously, and leave her so prostrated and anemic that it was thought she could not rally. She had lost thirty pounds in weight, and was blanched in appearance. He would confess that he was surprised to find, on examination, that his patient had a polypus not larger than a Concord grape; but the mucous membrane of the cavity of the uterus was hypertrophied and granular. The pedicle was attached far up in the cavity of the uterus. The tumor was removed by means of the curette. The patient now menstruates regularly.

This case contrasted strongly with the three others in its hæmorrhagic character, and it presented the history commonly met with in these growths. There was no doubt that the location of the tumor had great influence in the causation of hæmorrhage in these cases—much greater than the size of the growth; but much also depended upon its histological character and the condition of the endometrium. Thus, when a fibroid tumor or polypus was situated in the cavity of the uterus proper, more hæmorrhage was likely to result than when it grew from the tissues of the cervix, because, if located in the former position, it was often of the muscular variety and therefore more vascular, and the mucous membrane of the uterine cavity, which was the direct source of the hæmorrhage, was usually hypertrophied and granular, as in the last case narrated. Moreover, when the cavity of the uterus was the seat of a polypus, the uterine and pelvic circulation was stimulated by its presence, somewhat in the manner in which it was affected by the presence of a fecundated ovum which had been blighted; it was a foreign body and the uterus tried to expel it, but by the effort the circulation was excited in that direction and hæmorrhage resulted. His first case, however, furnished an exception to the rule that hæmorrhage attended when the tumor occupied the uterine cavity, but, as tenesmus was present, it was possible that hæmorrhage might have occurred subsequently, had the tumor been allowed to remain.

Dr. WILLIAM GOODELL remarked that the question of hæmorrhage in cases of polypi was a curious one. It seemed less likely when the tumor was in the body of the uterus, and checked the amount of circulation by exciting tonic contractions, than when it was protruding into the vagina like the clapper of a bell. In one case, where the hæmorrhage had produced extreme anæmia, dialysed iron was given to relieve the anæmia, and it also checked the hæmorrhage. In another case an operation was declined, and death resulted from hæmorrhage three days after the visit.

Rapid Dilatation of the Uterine Canal.—Dr. GOODELL read the following paper:

For many years I enlarged or straightened the uterine canal, according to the requirements of the case, either by tents or by Sims's operation, and preferably by the former. Having had several serious warnings in the shape of inflammation following these operations, I began to perform them with fear and trembling. Yet nothing very untoward happened until the year 1878, when two grievous mis-haps befell me.

A charming young lady, the center of a large circle of admiring friends, came from a neighboring State to consult me about

a dysmenorrhœa which grew worse and worse every year. The cervix was so bent forward, and the stenosis of its canal, *per se* as well as by angulation, was so marked, that I unhesitatingly performed Sims's operation. Within a few days septicæmia set in, soon the parotid glands swelled up, and on the ninth day she died. True it is that, at the same time, two piles also were tied, but this latter operation I had, and have, performed so many times with impunity that I was, and am still, disposed to attribute the blood-poisoning to traumatism of the cervix and not to that of the rectum. Hardly had I time to recover from this bitter blow when a case of exhausting menorrhagia fell into my hands. The lady was the young bride of a husband well advanced in life, who doted on her as only old men dote on much younger wives. I dilated the cervical canal with tents and curetted many vegetations from the endometrium. A furious peritonitis set in, and in less than three days this young wife lay dead and the husband was frantic with grief.

The anguish which I felt at the death of these two ladies, and the heartrending scenes which I witnessed at their bedside—scenes which I can not now recall without emotion—urged me to try any remedy that gave promise of efficiency combined with greater safety. In the search for a substitute, I tried rapid dilatation, which Ellinger and others had proposed, and since that year—that *annus ira*—I have not once performed Sims's operation for dysmenorrhœa, and I have so narrowed the field for the use of tents that I now very rarely resort to them. In short, rapid dilatation has proved, in my hands, so safe and so efficient an operation that I wish to urge its claims before this society.

The instruments which I would recommend are two Ellinger dilators of different sizes. These are the best on account of the parallel action of their blades. The smaller of these dilators has slender blades, and it pilots the way for the other, which is more powerful and with blades that do not feather. I have had the beaks of these dilators changed from an obtuse angle to a slight curve, so that it can be reversed within the womb. The lighter instrument needs only a ratchet in the handles, but the stronger one should have a screw with which to bring the handles together. Lest the beak should hit the fundus uteri and seriously injure it when the instrument is opened, the blades are made no longer than two inches, and are armed with a shoulder which prevents further penetration. The larger instrument opens to an outside width of an inch and a half, and it has a graduated arc in the handles by which the divergence of the blades can be read off. The instruments which I now exhibit to you, and which I can recommend highly, have been made, under my supervision, by Messrs. J. H. Gemrig & Son, of this city.

In a case of dysmenorrhœa or of sterility from flexion or from stenosis, my mode of performing the operation of rapid dilatation is as follows: The patient is thoroughly anesthetized, and a suppository containing one grain of the aqueous extract of opium is slipped into the rectum. She is then placed on her back and drawn to the edge of the bed, the knees being supported by her nurse. The light must be good, so that the operator may clearly see what he is about. By the aid of a strong tenaculum, applied through my bivalve speculum, the cervix is steadied and the smaller dilator is introduced as far as it will go. Upon gently stretching open that portion of the canal which it occupies, the stricture above so yields that when the instrument is closed it can be made to pass up higher. Thus by repetitions of this manœuvre, little by little, in a few minutes' time a cervical canal is tanneled out which before could not admit the finest probe. Should the os externum be a mere pin-hole, or be too small to admit the beak of the dilator, it is enlarged by the closed blades of a straight pair of scissors, which are introduced with a boring motion. As soon as the cavity of

the womb is gained the handles are brought together. The small dilator being now withdrawn, the larger one is introduced and the handles are then slowly screwed together. If the flexion is very marked, this instrument, after being withdrawn, should be re-introduced with its curve reversed to that of the flexion, and the final dilatation then made. But in doing this the operator must take good care not to rotate the womb on its axis, and not to mistake the twist for a reversal of flexion. The ether is now withheld, and the dilator kept *in situ* until the patient begins to flinch, when the instrument is closed and removed. A few drops of blood trickle out of the os. Occasionally a slight flow of blood will last for several days after the operation, simulating the menstrual flux. Often this flux is precipitated or renewed if the operation follows or precedes it too soon. The best time for dilatation is, therefore, midway between two monthly periods.

When compared with the cutting operation, this one looks like rough usage, yet the woman rarely needs more than two or three suppositories, and complains merely of soreness for one or two days. To forestall any tendency to metritis, she is kept in bed until all tenderness has disappeared. Pain is met by rectal suppositories of opium and by large poultices laid over the abdomen. I have seen slight pelvic disturbance arise from this operation, but it has always been readily controlled and has not given alarm.

In the great majority of cases I dilate the canal, not to the fullest capacity of the instrument, but to one inch and a quarter. Sometimes in an infantile cervix which does not readily yield and might give way, the handles are not screwed down more than three quarters of an inch or an inch. Tearing of the cervix has happened in two of my cases. In one, that of a virgin, the cervix was split half-way down to the vaginal junction. The other case was that of a multipara whose uterine canal had been nearly closed up by applications of silver nitrate, made by her physician, with the view of curing what he supposed was an "ulceration of the os," but which was a bilateral laceration. The tissues, rendered cicatricial and brittle by the caustic, were torn by the dilator for about half an inch on the right side also. Here the hæmorrhage was free enough to need styptic applications and a tampon. I could have stopped it by wire sutures, but this was not done, as it would have defeated the object of the operation.

For slight dilatations, such as for the office treatment of ante-flexions and of stenosis, or for the introduction of the curette, or of the applicator armed with cotton, the more delicate instrument is quite strong enough, and an anæsthetic is not needed. Sometimes, in a very sharply ante-flexed womb, the dilator can not be made to pass the os internum. This difficulty is overcome by first passing in a surgeon's probe, and then, along it as a guide, the dilator. After a forcible dilatation under ether, the cervical canal rarely returns to its previously angular or contracted condition. Since lateral extension of elastic bodies antagonizes their length, the cervix shortens and widens; and the plasma, provisionally thrown out by the submucous lesions sustained by the dilated part, serves still further to thicken and stiffen its tissues. In other words, the stem-like neck of the pear-shaped womb is shortened, widened, strengthened, and straightened. Hence, for straightening out ante-flexed or congenitally retroflexed wombs, and for dilating and shortening the canal in cases of sterility or dysmenorrhœa arising from stenosis or from a conical cervix, the dilator will be found a most efficient instrument. In its results it is not infallible; I have twice been obliged to repeat the operation, and would have liked to do so in several other cases had the woman permitted it. In a very few instances I have been forced, as a final resort, to nick a pin-hole os externum; but I had not then learned how far

I could safely stretch-open the uterine canal, and the operation of dilatation was not so efficiently performed by me as it is now through a larger and riper experience.

But it is not to cases of dysmenorrhœa that I limit the operation of rapid dilatation. As stated before, I use it to stretch open the canal for the admission of the curette and of spongetents, or for the purpose of making applications to the uterine cavity. In cases needing irrigation of the uterine cavity, I first dilate the canal with this instrument, and introduce the nozzle of the syringe between the separated blades. This gives a free avenue for the escape of the liquid, and robs of its dangers this form of intra-uterine medication. I also resort to the dilator in order to explore the womb with the finger. For instance, in any given case of menorrhagia in which a polypus or some other uterine growth is suspected, instead of using tents, I put the woman under an anæsthetic, and, after the rapid dilatation of the cervical canal to the utmost capacity of the instrument—viz., one inch and a half—am enabled to pass my finger up to the fundus. This is accomplished either by drawing down and steadying the womb by a volsella forceps, or, in thin subjects, by forcing the womb down upon the finger through supra-pubic pressure on its fundus. In this way I have, over and over again, at one sitting discovered a uterine growth, twisted it off, and removed it. Usually in these cases I experience more difficulty in removing the polypus or other growth through the small canal than in twisting it off from its uterine attachment. It often has to be wire-drawn before it can be removed, and sometimes the os uteri has needed a few nicks. Usually, when the menorrhagia is free, the cervical tissue is so loose that there is no difficulty in the introduction of the index-finger up to the fundus, but sometimes only its tip can be made to pass the os internum. Yet, even this limited degree of penetration is commonly quite enough to decide the presence of an inside growth. If it is not enough, I invariably search for a growth with a small pair of fenestrated forceps; and I have repeatedly seized and removed one the existence of which was merely suspected. After such operations the uterine cavity is thoroughly washed out with a solution of carbolic acid or of potassium permanganate.

I am sorry to say that I have not kept full records of all my cases of rapid dilatation. For instance, I have never recorded those office cases of dilatation in which ether was not given. Nor has any note been made of cases in which dilatation was performed under ether for curetting, for digital exploration of the endometrium, or for the removal of uterine growths. I have tabulated merely cases of dysmenorrhœa in single or in married women. In the married, with but three exceptions, which will be noted, painful menstruation was accompanied by sterility.

Including all the cases of dilatation performed under ether, I must have had over three hundred. I have limited myself to these cases because the use of an anæsthetic implies full dilatation—one in which serious injury, if ever, would most likely be sustained. Yet there has not been a death or a case even of severe inflammation in my practice, and the results have been most satisfactory—far more so than when the cutting operation was performed by me. The following are the statistics of my cases of dysmenorrhœa:

Unmarried.....	80
Married	88
	<hr/>
	168

Of the unmarried, eighteen were unheard from after the operation, leaving sixty-two from whom any data could be obtained. Of these, thirty-eight were cured, seventeen more or less improved, and seven not improved at all. Of these seven that

were not benefited by the operation, five subsequently had their ovaries removed—one of them by another physician and four by myself; of the latter, one died. In each one, the ovaries had become so altered by cystic or by interstitial degeneration as to make the dysmenorrhœa otherwise incurable. Of the seventeen improved, there was one on whom oöphorectomy was also performed; for, although the dysmenorrhœa was greatly relieved by dilatation, ovarian insanity and menorrhagia were not. The operation was a successful one, and my patient not only was cured of her hæmorrhages, but regained her reason. Out of these patients, the majority, although not wholly cured, were greatly improved. For example, one of them was formerly bed-ridden during the whole period of her menstrual flux, and had then to take large doses of morphia. She also suffered at those times from hæmatemesis and epistaxis. Since the operation she experiences pain for merely two hours, needs no anodyne, and has lost her ectopic hæmorrhages. Her gain in health and flesh has been great. Another one, who was wholly crippled by her sufferings and made nervous by the dread of them, is now a busy nurse. For one hour at every period she suffers a great deal, but she is too much afraid of taking ether to have a second dilatation performed.

Of those cured, two had Sims's operation performed previously without benefit, and were afterward dilated; two were dilated twice before a cure could be brought about. The history of several cases merits more than a mere allusion. The sufferings of one of my patients at every monthly period had always been great; but while she was at a boarding-school they grew so intense as to cause furious delirium at those times. This finally developed into permanent insanity with suicidal impulses. While in this condition she was placed in my hands. After rapid dilatation of the cervical canal, the dysmenorrhœa wholly disappeared. The exemption from pain toned down some of her more extravagant delusions, but she did not wholly regain her reason until a few months afterward. She is now free from all menstrual pain and in the complete possession of her mental faculties.

A Hebrew lady whose health had suffered from dreadful dysmenorrhœa was improved so much at one sitting that her physician and friends were amazed. Not long afterward he asked me to perform the same operation upon another one of his patients, who was, if anything, worse. Her sufferings were so intense that he wrote, "I fear that another period might kill her," and urged an immediate operation. The cervix in this case was conical and very dense. Fearing a tearing of the parts, I screwed the instrument slowly up to one inch and a quarter, and kept up this amount of dilatation for some twenty minutes. The cervix sustained no injury. The canal has since remained patulous, and she is free from all menstrual pain.

Of the married, fifty-three were heard from. Of these, thirty-nine were cured, ten improved, and four unimproved. Out of these fifty-three patients, nine were not in a condition to conceive—three of them from fibroid tumors, two from destructive applications of nitrate of silver to a lacerated cervix, three from being over forty-one years of age, and one from being a widow. This leaves but forty-four capable of conception, and of these, eight, or a little over 18 per cent., became pregnant. But the ratio is in fact larger, for several of my patients, fearing pregnancy, employed preventive measures after the operation. Then, again, I believe that others who consulted me merely for painful menstruation have not reported their subsequent pregnancies. For instance, two months ago I learned through the merest accident that the wife of a clergyman, whose cervical canal I dilated six years ago, has since been making up for lost time by giving birth to twins within a year after the operation, and then to several other children. She had been married eight

years before she came to me, and had had her cervical canal dilated by tents and slit up with Peaslee's metrotome by a skillful surgeon. I have also had several cases of pregnancy following office-dilatations of the uterine canal, in which ether was not given, and consequently the lumen of the canal was not much enlarged. But such slight operations were not deemed worthy of record, and they therefore have no statistical value.

Dr. HARRIS inquired about the danger of lighting up a former oophoritis by dilatation. The operation was successful, but that was its danger.

Dr. GOODELL had not hesitated to operate, but always used opium first, and by the time the operation was over the patient was under its influence. He kept them in bed and under the opium until all tenderness had passed entirely away.

A Dermoid Cyst of the Ovary was shown by Dr. GOODELL. A saleswoman, aged twenty-seven, was obliged to give up her situation because she found herself unable to stand for any length of time. Her physician discovered a pelvic tumor, and called in Dr. Goodell to see her. The diagnosis was obscure, but he leaned to a fibroid degeneration of the right ovary. The woman was otherwise well, suffering no pain whatever except when she was in the upright posture. The operation was performed on September 8th, and the tumor turned out to be a dermoid cyst. Being enveloped in the broad ligament, it was removed with difficulty. It was found stuffed with hair, and contained a plate of bone, the sharp edge of which had been readily felt *per vaginam*; but it threw no light on the diagnosis, as it was mistaken for a fibroid spur. His patient did uniformly well, and was now out of bed. He stated that in his experience these tumors were very vulnerable and often resisted even so slight an operation as aspiration, inflammation and suppuration quickly setting in. A physician had to-day brought to his office a young woman who had been tapped last June with a trocar. Long hairs and much sebaceous matter escaped through the opening, which had not yet healed up, and it was for this reason that he had been consulted. Upon passing in a uterine sound he struck a foreign body, which, from its density and the sharp click it gave, he was disposed to think was a tooth. He advised dilatation of the fistulous tract and the removal of the offending body.

Two Cases of Oophorectomy.—Dr. GOODELL also exhibited the ovaries which he had removed on September 17th and 29th from two patients, who also were doing well. He stated that the amount of tissue-change in these ovaries was very slight, and yet the suffering of each patient had been great. One had been an invalid for several years, and bedridden for the past six months. She had lost much flesh and was always groaning from left ovarian pain unless under the influence of large doses of morphia administered hypodermically. The left ovary was found to be undergoing cystic degeneration, but the right one was so sound that in its removal he was glad to have the backing of Professor W. S. Playfair, of London, who was present at the operation, for he believed that in most cases needing oophorectomy the results usually showed failures unless both ovaries were removed and the menopause was established. Convalescence after the operation had been retarded by great and painful swelling of both parotid glands, which developed without any marked rise in the temperature and without acceleration of pulse, and declined without suppuration—behaving exactly like mumps. This made his third case of parotitis following the removal of the ovaries. Not one had ended fatally, and, from the very slight febrile movement, he thought that the complication was not symptomatic—as in blood-poisoning—but sympathetic, and that a strong kinship, recognized by laymen, existed between the sexual organs and the cervical glands. Since the operation all pelvic pain had ceased.

The other patient was a poor woman, aged thirty, the mother of seven children. She was sent to him by Dr. George S. Hull, of Chambersburg, Pa. Three years ago she began to suffer from double oöphoralgia. The pain never left her wholly, but it began to increase in severity a week before the period culminated during the flux, and faded off afterward. Large doses of anodynes were needed in this case also, and she was unable to work. The case was clearly one of ovarian dysmenorrhœa, and he believed she would be permanently cured.

Dr. CHARLES H. THOMAS asked Dr. Goodell his experience of the result of oöphorectomy. What proportion of patients were relieved?

Dr. GOODELL could not reply definitely. He intended to report his cases before this society at some future time. In the majority of cases menstruation ceased, and, that element of trouble being removed, the patient was to that extent always improved. The neurasthenia resulting from previous suffering might remain, but it was far more amenable to treatment after the cause had been taken away. One such case had occurred to him recently. Dysmenorrhœa caused a virtual insanity, with a mind constantly wandering. The removal of the ovaries at once cured the dysmenorrhœa. The patient was now able again to walk, and the mind was improving. The operation removed the major element.

Dr. THOMAS had now in his care a case which he thought typical. The patient was a literary woman, overworked and crushed by family anxieties and depressing emotions. He prescribed rest and feeding. Massage proved of but little use, and electricity yielded negative results. Forced feeding became impossible. During menstruation she suffered for two or three hours with moderate dysmenorrhœa. Signs of oöphoritis developed, with swelling and hardening in the right iliac region. The patient was etherized, and a careful examination resulted in finding nothing materially wrong. As soon as anæsthesia was complete all the induration and tumefaction disappeared. There was an ulcer of the rectum, with moderate anteflexion of the uterus. The ulcer had since been cured, but there was no sensible relief. She suffered from a violent pain in the right ovary, extending to the coccyx and across the abdomen; it was cutting in its character at all times, and terribly severe. Formerly it ceased at night, but did not now. Hypodermic injections of morphia night and morning were necessary. Riding increased the pain, which often extended down the right leg. She could not sit up long without increasing the pain, which was evidently getting worse day by day. She had been totally disabled for nearly ten months. Was this pain hysterical? Could it be relieved by oöphorectomy?

Dr. GOODELL remarked that the question of oöphorectomy was, in any case, one requiring serious consideration. In the cases just related by him the patients had neither the means nor the time for prolonged treatment. Whenever possible, everything should be tried before resorting to an operation. One bedridden patient under his care, very analogous to Dr. Thomas's, had been relieved by the long-continued use of the constant current passed through the affected ovary. A feeble current was kept up for many hours, sometimes for a whole night at a time. The patient ultimately got well, bore several children afterward, and was now earning her living by teaching.

Observations from the Study of 142 Cases of Hysterotrachelorrhaphy.—Dr. CHARLES MILES WILSON read the following paper:

Though much has been written on this subject in the past few years, I trust a description of special instruments and a summary of the histories of 142 cases will not be amiss. In view of the exhaustive treatment the subject has received at the

hands of many observers, I hesitate to report my own limited experience. One hundred and four of these cases occurred in the practice of Dr. E. Wilson, two in my own, and the balance I witnessed as assistant, either in hospital or private practice. I regret that circumstances prevented me from obtaining a full history in all the cases. No one should hesitate to perform the operation or be unable to recognize the lesion. Yet very frequently gynecologists have sent to them, either for an opinion or operation, cases diagnosed as eroding ulcers, fungoid vegetations, cancer, etc., which, when the patient is properly examined, prove to be cases of laceration. The touch alone is sufficient to establish the existence of the lesion. If corroborative evidence is required, the patient should be placed in the knee-chest position, and the uterus exposed with a Sims speculum. For in this position, if each everted lip is grasped with a tenaculum, by gentle manipulation the natural contour of the cervix can be restored. If this simple feat can be accomplished, the diagnosis is at once established. For, in malignant disease, ulcerations of the os, etc., this can not be done. Reeves Jackson considers this test infallible. Formerly, many cases of laceration were comprehended under the generic term ulcer. But the description of the lesion and the operation by Dr. Emmet has settled for ever the well-worn controversy which so long divided medical opinion concerning the aetiology and pathology of the so-called ulceration of the cervix uteri. Oftentimes useless and injurious applications are made to the cervix, because the gentlemen having the medical care of the cases do not understand that the cervix is torn.

The old-fashioned tubular speculum is still too frequently used. It is now generally conceded that it is useless, except where *harsh* treatment is to be applied to the cervix without injury to the vagina. The tubular speculum separates the already everted lips and makes the laceration assume a more angry appearance. Thus faulty methods of examination often obscure the diagnosis. Another difficulty with many physicians is that the symptoms of which the patient complains are too apt to be regarded as the expression of some malady in which the uterus is not involved, unless, indeed, they complain of some vaginal discharge (a condition rarely absent). Again, the train of symptoms which belongs to laceration belongs equally to many other uterine ailments, and nothing but a carefully conducted examination can demonstrate that such is the case. The anæmias, debility, and other results of laceration, like the results of many other pathological conditions of the pelvic viscera, are often treated by a course of tonics, while the underlying cause of all the mischief goes on with its destructive work. When a woman consults a physician, complaining of any of the more marked symptoms, such as cranial, rectal, vesical, or pelvic pain, a feeling of weight about the uterus, disordered menstruation, and a leucorrhœal discharge, a vaginal examination should be considered an "imperative and essential prerequisite to treatment." The best of investigators is always at hand, namely, the index-finger, of which one of the masters of gynecological surgery says: "When properly educated and used to the full extent of its capacity, there is hardly any of the pathological conditions of the pelvic organs in woman which can escape its detective powers." Simpson in England, and Gardner in this country, first called attention to lacerations of the cervix. Emmet, as he himself says in his book, accidentally discovered the lesion in 1862, and devised the operation for its relief. To him belongs the credit of revolutionizing gynecological surgery.

Parturition is the chief cause of the lesion. The pressure of the child's head alone, especially if it is a large one, upon the os, may, even in a normal labor, be sufficient to lacerate it. If the os is rigid, or, as frequently happens, is both rigid and attenuated, the danger is of course increased. If the longitudinal

and oblique fibers of the uterus have greater contractile force than the circular fibers of the lower segment of the uterus have expansive power, the force of the contractions of the former exerted upon the foetal body, which rests upon and is engaged with the latter, may lacerate them owing to their non-expansion. In premature labor the circular fibers of the os, not being ready for the dilatation necessary to permit the egress of the contents of the uterus, may give way—i. e., there may be sufficient irritation of the uterus to expel its contents by contracting the fundus, but not enough to expand the os. Meddlesome midwifery is a prime cause. By this term I mean the practice of trying to force back from the presenting portion of the child the margin of the os, without waiting for it to dilate properly; the desire to expedite the labor in every possible way, the premature rupture of the membranes—the physician forgetting that nature's dilator, the "bag of waters," is the best of all. Experience teaches that all labors in which the membranes have been ruptured prematurely, either accidentally or purposely, are apt to be complicated by some laceration of the obstetric canal, especially of the cervix. Unnecessary and unscientific application of the forceps, and traction made with it without a proper knowledge of the pelvic canal and outlet, is another factor.

That the forceps is responsible for many cases of laceration there can be no doubt. When applied high up, or within the uterus, it is exceedingly apt to produce tearing of the cervix. Observations made by Dr. Mundé, at Mt. Sinai Hospital, New York, showed 119 cases of laceration in 750 women examined. Dr. Hanks, of the Demilt Dispensary, found only eight per cent. troubled with laceration. The Mt. Sinai is a Jewish institution, and most of its patients are Hebrews; these are generally attended by midwives. The Demilt is patronized by the poor of the city generally, and the patients are mostly attended by young graduates, who frequently use the forceps. So far as these observations go, they show that the forceps, even in inexperienced hands, does not do as much to produce laceration as the often untimely interference of ignorant midwives. Professor Gross, in one of the last papers he ever wrote, spoke of the frequency with which the forceps was applied, strongly condemning this practice and very justly attributing many of the cases of laceration of the cervix to it. He formulated his views in the words, "The principal causes of laceration are precipitate labor—labor attended with rigidity of the mouth of the womb, and *instrumental* labor." Dr. Fundenberg, in an article which appeared in the "Pittsburgh Medical Journal," makes use of this positive language: "I believe that the forceps, when properly applied, is a preventive of laceration of the cervix. . . . When carefully introduced, for instance, into a rigid os, dilated only sufficiently to receive a narrow blade, the waters being discharged, it preserves the cervix, by its inclined plane, from sudden impulse, and, simulating the bag of waters in its wedge-like and outward action, it dilates with great and continuous power, with any desirable amount of slowness, and with very great safety." In the 142 cases seen by the writer, the forceps had been used in 49—presumably, from the account of the patients, at the labor from which their distress dated. Did space permit, I should like to quote from other papers in reference to this question. Suffice it to say that the maladroit use of the forceps is responsible for many cases of laceration. The breech presentation is another factor, because of the necessity of rapidly delivering the head. The cervix may also be torn by the shoulders after the head has passed safely through. The injurious practice of giving large and frequent doses of ergot prior to the expulsion of the fetus is another cause. So, too, are abortions. The predisposing causes include the various forms of induration, whether caused by hyperplastic deposit or malignant

disease; all affections of the cervix producing tissue softening, such as epithelioma; or any condition interfering with the natural elasticity of the parts, as the cicatrices of previous surgical procedures, or, as happened in two of the cases the writer saw, of cauterizations; and any syphilitic or strumous taint, giving the uterus lack of tone. Dr. E. Wilson lays great stress on the "muscular depravity, the result of a constitutional syphilitic taint, and the consequent emaciated condition of os." This muscular degeneration may be the result of many pathological conditions—for example, anæmia, malnutrition, phthisis, and the like. Again, when the uterus is in a state of constant activity, owing to frequent gestation, it is liable to lose tone, and thus pave the way for the exciting cause to light up the trouble. Women are more apt to meet with this accident at the time of their first delivery than subsequently. It occurs also more frequently in rapid labors. Dr. Emmet believes that partial laceration takes place at the first delivery. Dr. Goodell, Dr. Pallen, and Dr. Mundé all record it as being exceedingly common. In two hundred women with uterine disease examined by the writer, nineteen had laceration of the cervix. The lacerations may extend through any portion of either lip. The writer has found the bilateral to be the most common—the rent being greater upon the left side—and laceration through the posterior lip the rarest form. The fact that a laceration has taken place is seldom noticed at the time of its occurrence.

When an examination is made at the completion of the delivery, the parts are so enlarged, soft, and yielding, and the os is so patulous that it is difficult to detect a laceration. But, if a tear has occurred, the woman soon begins to complain of symptoms which are well-nigh pathognomonic. Shortly after she rises from her bed and resumes her ordinary household duties she notices a more or less constant and generally increasing leucorrhœal discharge. This discharge is thick, viscid, and glairy, and sometimes tinged with blood. Sometimes, though rarely, this discharge is absent, or after a time disappears. Pain is a prominent symptom. It is generally of a dull and aching character. It is frequently referred to the lumbar region. Headache is a marked symptom. There is a peculiar sense of weight about the uterus, which is increased, along with the pain, after exertion. This feeling is augmented when the woman assumes the erect posture. The menstrual flow is, as a rule, increased. It is profuse, longer in duration, and comes on after shorter intervals. There is generally a nasty, glairy, and sometimes semipurulent discharge during the catamenial intermission. My own observation has taught me that there is generally an increase in duration and amount. When the laceration is recent, the increase is so small that it is hardly noticed, but, as a rule, it increases steadily until it sometimes assumes the character of a sudden and violent uterine hæmorrhage. Patients generally suffer with a feeling of malaise. The general health soon becomes impaired. The digestive system is often the first to suffer. Sexual appetite is usually impaired, sometimes abolished, its gratification being always attended with great pain. Insomnia is often present, together with other symptoms of a nervous character. The writer has seen one case in which hysteropilepsy was a prominent symptom. The symptoms are usually commensurate with the extent of the eversion of the lining membrane of the cervical canal. This membrane, when thus exposed, loses its delicate epithelial coat, and it chafes against the posterior walls of the vagina. This irritates and inflames the raw surfaces. Hypostatic congestion and engorgement ensue. This prevents proper involution of the uterus, and the parts remain enlarged and soft. The heavy uterus, inadequately sustained by its supports, falls to the floor of the pelvis, dragging the upper portion of the vagina with it. This makes the cervix look elongated, when in reality it is shortened. Sometimes

cicatization takes place, and often this plug of cicatricial tissue gives rise to symptoms more distressing than when the parts remain ununited. The mental symptoms are sometimes very grave, amounting to such a degree of mental perturbation as to threaten the sanity of the patient. One of Dr. E. Wilson's patients was for some months in an insane asylum. After her cervix was restored, her symptoms gradually subsided, and eventually, in the space of six weeks, entirely disappeared. This woman was deprived of her liberty because her friends refused to have the operation done. Another woman in his practice, a subject of melancholia with uterine symptoms, came very near being spayed. After her cervix was repaired, her melancholia and other symptoms vanished entirely. A very curious case of persistent salivation, apparently due to laceration, at all events which was cured by restoring the cervix, is reported by Dr. Longyear, in Vol. xvi, No. 1, of the "American Journal of Obstetrics." Did space permit, I might cite other interesting cases.

If the foregoing views in reference to laceration are correct, the indications for treatment are certainly clear. Having decided to resort to surgical means for the relief of his patient, the surgeon must consider whether the patient is in a proper state of health to be operated on. The same conditions which militate against other surgical procedures are equally operative in cases of trachelorrhaphy. When the uterus is bound down by adhesion, or severe inflammation exists, it is dangerous to operate. One patient who came under my observation nearly perished from an attack of peritonitis, because forcible traction was made to draw down to the ostium vaginae a uterus which was fixed and immobile, owing to adhesions, the result of a former attack of peritonitis. For operating, the patient should be placed in the dorsal posture, with her buttocks well drawn down to the edge of the table, an assistant taking charge of each limb. The cervix is exposed with a Sims speculum, grasped with a volsella, and gently brought to the ostium vaginae. The needle is passed through the cervix in the median line, from above downward; it is then armed with a stout piece of silk cord and withdrawn. A blunt-pointed tenaculum is then passed up the cervical canal until it engages the cord, a loop of which is withdrawn. This loop is divided, and the two free ends are united, thus forming two loops, the one controlling the anterior, the other the posterior lip. The margins of the tear are now freshened, care being taken to extend the line of incision beyond the angle of the rent, and to cut out any cicatricial tissue that may be present.

The hæmorrhage, which is never profuse, and which, by depleting the vessels of the uterus, tends to ameliorate the inflammatory conditions often present, is easily controlled by the application of hot sponges. Any one who has seen many operations must have noticed the sudden blanching and softening of the cervix due to the bleeding attending the operation. The late Professor Gross thought that the benefit of the operation was largely due to this local depletion. I have seen the circumflex artery cut on several occasions, but it never required a ligature to control it. Care should be taken to make the posterior angle of the plug of tissue removed sufficiently acute to allow of the proper approximation of the lips without tension in the sutures. The lower lip should be denuded first; otherwise, the hæmorrhage will obscure the field. Sufficient mucous membrane should be preserved in the center to re-form the canal. This is not always possible, and, when it can not be done, a small piece of carbolized lint should be inserted to prevent union in the line of the canal. This should be removed at the end of twenty-four hours. Otherwise, the canal may be occluded. This accident happened in three of the cases of Dr. E. Wilson's series, and the occlusion was overcome with some dif-

ficulty. All clots having been removed, and exact hæmostasis having been maintained for some moments, the wound is closed by inserting the needle through both lips, arming it with a wire suture, withdrawing it, freeing the wire, and clamping it with a shot. The ends are then cut off close to the shot. The sutures should be removed by the tenth day. As they are difficult to get at, these scissors were devised for that purpose. The vagina should be syringed out twice daily with a solution of the mercuric bichloride, 1 to 2,000. A Sims speculum should be used to remove the stitches, as there is danger of tearing the freshly united surfaces apart with a bivalve. In three cases I have seen excessive bleeding, all occurring on the third day after the operation. This, however, did not seem to come from the wound, but was regarded as the result of a passive congestion of the endometrium. If the operation is successful, the relief afforded is speedy and sure, and, what is more, generally permanent. The operation is simple and free from danger. It often renders sterile women capable of child-bearing.

Dr. E. Wilson has attended in confinement ten women on whom he had previously performed the operation. In two there was a slight recurrence of the tears. In many cases where coitus was impossible, on account of the pain and hæmorrhage it produced, the difficulty has been entirely overcome. In one case only did the operator fail to get a satisfactory result. The cervix was badly torn. It was repaired. The woman was afterward found to have salpingitis. Though her health improved after the restoration of the cervix, she did not recover. In a future communication to the society I hope to show her Fallopian tubes. Allowed to run its course, the sequæ of laceration are endless—disturbances of the catamenia, dyspareunia, oöporitis, leucorrhæa, subinvolution, grave mental disturbances, and, above all, epithelioma. In conclusion, gentlemen, permit me to quote the words of a distinguished gynecologist: "These are no longer the chimeras and hobbies of the specialist, but grave and serious dangers." It is to be hoped that in time to come a more scientific and certain knowledge of the dangers and difficulties of parturition, and of the means for their avoidance, may enable physicians to avert the accident.

Dr. BARE inquired if the operations were done for the relief of sterility.

Dr. Wilson replied that they were for the relief of general symptoms. Ten of Dr. Ellwood Wilson's patients had since become pregnant.

Dr. GOODELL remarked that he had no trouble in removing the stitches. His method was to leave the two lateral upper stitches with long-shotted ends; by means of these each side of the cervix could be drawn into the field of his bivalve speculum and the stitches removed with ease.

Dr. MONTGOMERY bore testimony to the same, and to the advantage of the bivalve speculum over Sims's for that purpose. He had used the double thread through the cervix, and had described its uses before this society at the meeting of October 6, 1881, as published in full in the "Obstetric Gazette" for January, 1882. As regarded the quantity of tissue to be removed in closing a laceration, the operator must be governed by the character of the injury, and it might not be possible to have a satisfactory result where there was an intversion of the uterus, the flexion occurring in the lower part of the cervix, the anterior lip being elongated and hypertrophied, the posterior normal or even atrophied; for in such cases it was impossible to prevent the preponderance of tissue in the enlarged lip. He could readily understand that, such a uterus becoming gravid, in the subsequent labor the long anterior lip would form a segment over the child's head, which would almost certainly result in relaceration. In the case which Dr. Wilson cited of extensive laceration during labor, the proper treatment would have

been to perform a primary operation by the immediate introduction of sutures, rather than permit the patient to be subjected to the necessity of a secondary operation. It would be necessary to introduce the sutures much deeper, and then to make allowance for the subsequent involution. It was not infrequent that multiple lacerations resembled epitheliomatous disease, and were accompanied by an offensive discharge. He had given temporary relief in such a case by the use of chromic acid and tannin locally. The needle used in passing the suture should not be much larger than the wire that was to follow it.

Dr. Wilson questioned the propriety of primary operations on the cervix, and thought the weight of authority against it.

Dr. MONTGOMERY remarked that the first case, by Montrose Pallen, was a primary operation and was successful.

Dr. THOMAS remarked that at the meeting of this society, held October 6, 1881, he had reported a case of laceration of the cervix uteri simulating cauliflower excrescence, which he had treated eighteen years before. The patient was exsanguine from hæmorrhage, which had put her life in great danger. He used glycerole-of-tannin tampons, and at the end of two weeks she had improved immensely and the condition finally proved to be a deep laceration with ectropion. Before the treatment she had been seen by six experienced gynecologists, who declared the condition cancerous, and one of them refused to be convinced that it was not so, saying, within the last four years, that it had been cancer, it was cancer, and she would die of cancer. When the case was reported, another of the physicians who had originally seen the case inquired of Dr. Thomas if he "proposed to cure uterine cancer by means of glycerole-of-tannin tampons." The menopause had since been established, the uterus, examined within the past month, was found atrophied, and the former patient had been for nearly twenty years a hard-working monthly nurse.

Dr. GOODELL thought it pardonable to make the mistake. With all his experience, he had seen two cases in which he could not for some time make a certain diagnosis. There was no doubt about the existence of a laceration, but whether the angry-looking growths were merely cock's-comb granulations or epithelioma was not so easy to decide. They eventually proved to be benign.

Miscellany.

THERAPEUTICAL NOTES.

Salicylic Acid as a Prophylactic against Cholera.—In a letter published in the "Bulletin général de thérapeutique," Dr. Beaudon says that his experience with salicylic acid as a disinfectant has been so satisfactory as to lead him to suggest that the drug be generally used as a prophylactic in case a country is threatened with cholera. He proposes the following rules for its use: 1. Make a solution of ten grammes of the acid in two hundred grammes of alcohol; add a teaspoonful of this solution to a glass of water. 2. Bathe, wash the hands, and rinse out the mouth several times a day with this mixture. Let all flannel and woolen clothing be impregnated with it. These precautions apply particularly to physicians, who are exposed to the contagion. 3. Take a teaspoonful of this same solution with each meal. The objection may perhaps be raised, he says, that the microbe (if there is a microbe) will be taken in by the respiratory passages. He does not discuss this idea, but limits himself to the statement that, whatever may be the channel of introduction of the microbe, it will not find a very fertile field for development if the individual has used and still uses a substance which opposes the entrance and propagation of the poison.

The Influence of Iodoform upon Body Weight in Phthisis.—Dr. Ransome ("Canadian Practitioner") administered to twenty-one patients

a pill containing one grain and a half of iodoform and two grains of croton-chloral three times a day. Three patients improved under the treatment; in five the disease progressed, but there was an increase in weight. In only two cases was the good effect persistent. Of twelve other patients who were treated in like manner, two became quite fat; in six there was no change after eight months; and four wasted away in spite of the treatment.

The Influence of Diet on Headache.—Haig ("Practitioner") reports at length a peculiar case of migraine which had long resisted treatment, and was finally cured only by strict adherence to a vegetable diet. Meat seemed to act upon the patient as a veritable poison.

The Treatment of Cardiac Troubles by Milk Diet.—Schmaubert ("Centralblatt für die gesammte Therapie") says: In giving milk, begin with a small amount, and regulate it according to the quantity of urine passed in twenty-four hours. The amount of milk must not exceed that of the urine. Milk is given in four doses during the day. All other food is strictly excluded. As regards the action of a milk diet on heart lesions, it is easily proved that its influence upon the anatomical changes is very limited; real improvement can only be obtained in fatty degeneration of the heart and dilatation of its cavities, especially if the latter is acute in its nature. On valvular lesions it exercises no influence. Hence the action of milk diet is limited to functional disturbances, but in this sphere it is unusually valuable; the influence is of a sedative and regulatory character, and manifests itself in slowing of the rapid contractions, diminution of the increased irritability of the heart, reproduction of the normal rhythm, etc. The precise regulatory action of the milk diet in cardiac diseases is probably due to a diminution of irritative influences from the stomach and intestines, as well as to diminished vascular obstruction and increased secretion of urine. A direct influence upon the heart can not be proved.

The Antipyretic Action of the Alkaloids of Quebracho.—M. Eloy and M. Huchard ("Union médicale") state that, in a series of thirty-six experiments upon animals, conducted by them, it was proved that these alkaloids (especially the one known as aspidospermine) exercised a powerful antithermic action. They have also employed hypodermic injections of aspidospermine successfully in cases of typhoid fever where quinine seemed to exercise no effect upon the temperature.

Corrosive Sublimate as a Disinfectant in Midwifery.—Dr. W. J. Sinclair, in the first number of the new "Medical Chronicle," gives a general résumé of the German contributions on this subject during the past year. The substance of his remarks is, briefly, as follows: Corrosive sublimate has largely replaced carbolic acid in several of the German lying-in hospitals, but there seems to be considerable diversity of opinion as to the value of the former substance and the dangers incurred by its free use. Stadfeldt, of Copenhagen, reports a death, with all the symptoms of mercurial poisoning, after a single intra-uterine injection of a solution of the sublimate, 1 to 1,500. Tænzler, of Breslau, states that he has used this solution freely in 624 cases, in four of which he observed symptoms of poisoning. He does not deny that there is danger in intra-uterine irrigation with corrosive sublimate, but suggests a means of avoiding it by firmly compressing the uterus after each injection, so that these shall be no longer laid in the cavity.

The Treatment of Puerperal Fever with Cold Baths.—M. Chobert, an abstract of whose inaugural thesis is given in "Lyon médical," draws the following conclusions from a number of observations made by him at the Lyons *Maternité*: 1. Cold baths can be safely administered in the puerperal state. 2. They are indicated in all cases of puerperal trouble attended with high temperature, with the exception of acute peritonitis. 3. We should begin with a bath of 28° C., and gradually lower the temperature until 18° C. is reached. 4. The baths are to be repeated every three hours until the temperature of the patient has fallen to 38° C., and remains there with slight evening oscillations. With the baths, large doses of alcohol are to be administered. The diet should be principally of a liquid nature.

Arsenic in Tuberculous Disease of the Joints.—Professor von Langenbeck ("Centralblatt für die gesammte Therapie") writes on the use of arsenic in cases of old tuberculous disease of the joints, where the patient has become greatly exhausted by long suppuration. He employs Fowler's solution, together with cod-liver oil, and speaks highly of this combination.

The late Dr. William Fruitnigh.—The following resolutions were passed by the Northwestern Medical and Surgical Society of New York, at a meeting held October 17, 1884:

Whereas, We, the members of the Northwestern Medical and Surgical Society, have been officially informed of the death of our friend and associate, William Fruitnigh, M. D., which occurred suddenly on July 20, 1884; therefore

Resolved, That we, as individuals and as a society, have lost a true and faithful friend. Our profession has lost from its ranks a member of great promise. Society has lost a useful and conscientious citizen; and it is with deep regret we mourn the loss of our esteemed brother. There is no time so mournful, none so solemn, as an occasion like this. Our beloved associate has been taken from us in the prime of early manhood, at an age when life and hope were most endearing. We mourn to be so suddenly deprived of our friend and brother, whom we had learned to prize and love. He was so manly and true, so sincere and kind, so noble, and withal so competent in the field of his chosen profession. But the laws of Nature are inexorable; death is as natural as birth. Nobly he performed life's mission and has gone to fathom the mysteries of eternity.

Resolved, That we extend our warmest sympathy and condolence to his bereaved parents and sister, and especially to his brother, our honored Secretary, J. Henry Fruitnigh, M. D.

Resolved, That these resolutions be entered upon our book of records, and a page be appropriately inscribed and dedicated to his memory.

Resolved, That the foregoing be furnished to the medical press for publication, and that an authenticated copy thereof, properly engrossed, be forwarded to the family of deceased.

WILLIAM M. McLAURY, M. D.,
C. A. LEALE, M. D.,
C. S. WOOD, M. D.,
} Committee.

Stigmata Maidis.—"Among the new remedies with which the materia medica has of late years been enriched," says the "Therapeutic Gazette," "there are few which have sprung into greater prominence, and which manifest evidence of a more tenacious hold on the regard of the medical practitioners, than the stigmata of maize—the 'silk' which embellishes the stalk of our common corn. It may seem somewhat incongruous to call an article with which the people of this country have been so long familiar a 'new' remedy. The adjective, however, as in the case of many other new remedies, so called, has reference rather to the discovery of some therapeutic property than to the drug proper. Corn-silk is, therefore, a new remedy from the fact of the comparatively recent discovery of its properties as an emollient, antiseptic, and diuretic. Under its lenitive action the inflamed surface of the genito-urinary tract, and more particularly, perhaps, of the bladder, as in vesical catarrh, is soothed, and the decomposition of urea into the irritant ammonium salts is checked. The flow of the urine is at the same time augmented, and thus we have a combination of the very effects which an intelligent comprehension of a case of vesical irritation would seem to dictate on the part of the therapist."

"The demand for corn-silk has been rapidly growing since attention was first called to it by Dr. Dassau and Dr. Dufau, of Paris, and Professor Castan, of Montpellier. The fluid extract must be made from the recent drug, and hence can be prepared only during a few months in the year. The demand, however, for this fluid extract has been in excess of the possible supply during the past year, leading to the substitution, by unscrupulous manufacturers, of a worthless article for the freshly gathered corn-silk, much to the detriment of the reputation of this drug. Messrs. Parke, Davis & Co., who were the first to place a preparation of stigmata maidis before the profession of this country, with the return of the season have laid in a large supply of the drug in anticipation of a continuance of its popularity. Competent employees of this enterprising house have for some time been at work in the corn-fields of the West, laying in a stock of the green drug, and suitably preparing it for preservation until it is made up into the form of a fluid extract. In view of the facts above stated, it is important that those who may have occasion to employ corn-silk may know whence they may obtain a reliable preparation."

AN INQUIRY INTO THE ORIGIN OF THE USE OF THE LIGATURE IN THE TREATMENT OF ANEURYSM.*

By LEWIS A. STIMSON, M. D.,

PROFESSOR OF CLINICAL SURGERY IN THE MEDICAL DEPARTMENT OF THE
UNIVERSITY OF THE CITY OF NEW YORK.

AMONG the many great advantages modern methods of treating wounds have conferred upon the art of surgery, one of the greatest is the security they have given to operations upon the arteries. They have made it possible to tie the principal arteries of the limbs in continuity with almost absolute security against secondary hæmorrhage, and with greatly diminished risk of causing gangrene. They have almost entirely done away with, or have relegated to the class of exceptions, that host of alternative methods by which for a century surgeons have sought to replace the ligature in the treatment of external aneurysms. It has become so safe to tie the femoral artery, for example, that the surgeon who, in an ordinary case of popliteal aneurysm, should resort to that operation in preference to any other method, would not be deemed indifferent to his patient's best interests, or thought to have exposed him to any serious risk which might have been safely avoided. The efficiency, promptness, and painlessness of the method would be accepted as a complete equivalent for the advantages peculiar to such rival methods as digital pressure or the use of the elastic bandage.

Such being the case, the question of priority in the introduction of the ligature gains in interest, and it is to that question that I ask your attention—a question that has been made to turn, not upon the simple fact of priority in the use of the ligature (concerning which there is no obscurity), but rather upon the motives, principles, and knowledge that guided those who first used it and who established the method. The facts are as follows:

On the 30th of January, 1710, Dominique Anel, a French surgeon practicing in Rome, operated upon a priest for a very large aneurysm of the brachial artery at the bend of the elbow, caused by an unskillful venesection; he exposed the artery above the tumor, and tied it as close to the latter as was possible; the patient made a good recovery.

The report of the case provoked much discussion, and a spirit hostile to Anel and to the new method showed itself in the country of his adoption, and it was charged against him, with a variety that testifies to the ingenuity of his detractors, that the case was not an aneurysm, that he had not cured it, and that the cure was only by a lucky chance. Against the first two charges he brought the written testimony of other surgeons who had seen the case; and against the third he offered arguments which show his correct apprehension of the manner in which the operation effects a cure. He says: "I did not touch the sac at all,

not doubting that the blood would leave it, since the way was open for it to pass down the limb, and that the sac, once emptied, would not refill; that the tissues of the membranes which formed it would not fail to shrink, and that thus the tumor would disappear; which did not fail to take place as I had expected."*

The case, together with his reply to various criticisms, was published by Anel in 1714, and the account was republished in various journals and books in 1716, 1739, 1749, and 1750; and the operation appears to have been repeated three times upon the brachial artery and once upon the temporal; in one of them the artery was tied "on the inner side of the arm above the condyle"; in all the aneurysm was traumatic.

The question at once arises: Why was not this method at once accepted by the profession and generalized? The answer is to be found, I think, in the attitude of the profession toward aneurysms in general, and in the ignorance of the existence of the collateral circulation. At the time Anel operated, surgeons attempted the cure only of traumatic aneurysms of the brachial and temporal arteries following venesection; against popliteal and femoral aneurysms they knew of no resource except amputation of the limb, and they had yet to learn even that the femoral artery could be tied without causing gangrene of the limb. One man (Morel, 1687) had applied the old method to a carotid aneurysm, but his patient died on the table, and the case served as a warning, not as an encouragement. The old method of laying open the sac and tying all bleeding points could be practiced without much difficulty and very successfully upon these minor aneurysms, and, although Anel's method recommended itself as easier of execution, it was, on the other hand, less certain to cure, because many of these aneurysms were arterio-venous aneurysms, and persisted or recurred after ligature of the artery. In two of the four cases above mentioned the disease returned, probably for this reason. In short, as regards some of the cases with which the surgeons of that time had most frequently to deal—arterio-venous aneurysms at the elbow—they possessed and successfully practiced the operation which to-day is still used in similar cases; and as regards the others, traumatic aneurysms of the brachial and temporal arteries, the same method was efficient; and, although the offered substitute was simpler, this advantage was offset by its failure when the aneurysm was arterio-venous; and they did not recognize the cause of the failure, for they had not learned to discriminate between this variety (first described by William Hunter in 1757) and the ordinary aneurysm. They labored under no embarrassment, no great difficulty from which

* "Car au lieu que l'on a accoutumé de faire la ligature en haut et en bas de l'anevrisme, je ne la fis, dit il, que du côté du haut: d'ailleurs, on ouvre le sac aneurismal, et je ne l'ai point touché du tout, ne doutant pas que le sang contenu dans ce sac ne se dissipât, ayant la liberté de se porter du côté de l'extrémité, et que ce sac étant une fois vuide, ne se rempliroit plus de nouveau, que les tuniques des membranes qui le formoient, ne manqueroient pas de s'affaisser, et qu'ainsi la tumeur devoit disparaître, ce qui n'a pas manqué d'arriver de même que je l'avois pensé."—Trévoux, January, 1716, p. 163; reprinted in "Bibliothèque choisie de méd.," 1749, vol. ii, p. 472, art. "Anévrisme."

* Read before the New York Surgical Society, October 14, 1884.

his operation could relieve them; it even exposed them to a variety of failure which they had not before known—the persistence or recurrence of the disease—and their knowledge of the resources of nature was not sufficient to enable them to extend their field of operation. What wonder that the new system was neglected and forgotten!

During the following half-century surgeons learned that it was not necessary to amputate the leg of a patient because the femoral artery was wounded; ligature of the wounded artery had been successfully practiced as early as 1646, and again in 1688, but it was not formally proposed as a substitute for amputation until nearly a century later. And, at about the same time, the "old operation" was first employed in a case of popliteal aneurysm successfully (Keyser, 1744), and, twenty years later, again successfully for femoral aneurysm (Burchell, 1765).

The attention of surgeons was now fully directed to the treatment of spontaneous aneurysms of the lower extremity, to the search for a proper substitute for the amputation which before had been the only resource. The first substitute was to extend to them the old operation, to repeat in a somewhat modified form what had been done by Antyllus more than fifteen hundred years before. Papers were written to prove that the obliteration of the artery would not cause the limb to fall into gangrene, and experience by actual operation rapidly accumulated.

The results of that experience were far from satisfactory. Pott ("Surgical Works," edited by Earle, vol. iii, p. 220) says of this operation: "I have tried it myself more than once or twice—I have seen it tried by others; but the event has always been fatal. . . . Nor have I ever seen any other operation than that of amputation which has preserved the life of the patient"; and, as Mr. Holmes points out, the immediate success of the treatment of popliteal aneurysm by proximal ligature (the "Hunterian" method), which itself has a mortality equal to that of amputation of the thigh, shows that the mortality after the old operation must have been something frightful. Something better needed to be found, and the times were growing ripe. Men were beginning again to think; the long blank period of tradition and dogmatism was coming to an end, and men stood at the threshold of the new era in which, under the influence of the intellectual upheaval of the French Revolution and the leadership of the French physicians, medicine was to become a science based on objective knowledge.

It had been learned that a popliteal or a femoral aneurysm could be cured by opening the sac and tying the artery above and below, but that the operation carried with it an enormous risk of death by secondary hemorrhage and the accidents arising from a large, irregular, suppurating wound. And, in describing the operation as incision of the sac and ligature of the vessel, it must be remembered that this order was frequently reversed and the artery tied before the sac was opened; the object was a double one: to close the vessel and to empty the sac, and the order in which these objects were attained was immaterial.

Desault's first operation of ligature on the proximal side was done June 22, 1785, and Hunter's December 12th of

the same year; but nine years before this, 1776, Desault* had had an opportunity to dissect a specimen of popliteal aneurysm that had undergone spontaneous cure, and he had found the popliteal artery plugged by clotted blood, the femoral obliterated "as far up as the origin of the muscular branches," and likewise the upper third of the tibial arteries. An Italian surgeon, Assalini, who spent a year in Paris, and a few months subsequently in London, and had the good fortune to see both Desault's and Hunter's operations in 1785, published a book† in 1787 in which he reports Desault's teaching in 1785; referring to this dissection of 1776, he says he [Desault] thought the obliteration of the upper and lower portions of the artery was the result of the stagnation of the blood in them, produced by plugging of the aneurysm, and that for this reason, in the treatment of true aneurysms of large vessels, he did not apply two ligatures and did not open the sac; he placed a single ligature above the aneurysm if that was possible, or below it if the condition of the parts made that necessary. By this simple ligature he prevented the blood from entering the sac and circulating in the dilated vessels.

This report is the substance of a clinical lecture given by Desault at the time of his first operation. It shows his conception of the method of spontaneous cure and of the means by which that method could be imitated; he sought to obtain coagulation of the blood through arrest of the current by placing an obstacle on either the proximal or distal side, and he knew—he had known for nine years—that it was not necessary to turn out the clots, that the incision of the sac could be dispensed with if the artery could be otherwise closed. But how was that to be done? Naturally enough, he first tried compression, and, that failing, then the ligature in continuity. Broca tells us that the first case of which we have knowledge that came under Desault's care was an axillary aneurysm, shortly before February, 1785, and he attempted to treat it by compression of the subclavian artery. Ligature of the subclavian was at that time an unknown operation. For some reason the patient left Desault and put himself under the care of another surgeon, who mistook the tumor for an abscess and opened it.

The idea of compression of the artery above the tumor was not new or unknown. In 1761 Kretschmer treated a traumatic aneurysm, resulting from a gunshot wound of the brachial artery, by direct pressure upon the tumor and by a tourniquet on the lower portion of the axillary artery; the latter was kept in place for three months, and the patient was completely cured. In 1765 Guattani treated a popliteal aneurysm by a bandage applied directly to the leg and tumor, and to the thigh over a long, narrow pad, placed along the course of the femoral artery, with the expressed intention of preventing, wholly or in part, the flow of blood to the tumor. And again, in September, 1785, at a consultation, held in London, on a case of femoral aneurysm as large as a middle-sized China-orange, at which eight surgeons (of whom Hunter was one) were present, all "were convinced of the impracticability of affording the patient

* Broca, "Des anévrysmes," p. 449, from "Journal de méd." (Vandermonde), vol. lxx, p. 473.

† "Essai médical sur les vaisseaux lymphatiques," Turin, 1787.

any assistance by the operation usual for aneurysms," and advised that the artery should be compressed at the groin; the attempt was made, but soon abandoned, because of the pain.*

We are now able to understand the position of the profession at the time; we know the extent of their knowledge, and with what problems they were dealing; we can put ourselves in Desault's place, interpret his act, and comprehend his motives. Let us see if that act was, as the partisans of Hunter claim, merely a lucky blunder, conceived in ignorance and passed without appreciation.

Desault knew an aneurysm could be cured without an incision to turn out the clot; he knew, as did most other surgeons, that the femoral artery could be tied without causing gangrene. He knew also that the principal cause of death after the common operation was secondary hæmorrhage, and the avoidance of this danger was his principal preoccupation, as it was also that of Hunter. We have seen that, far from trying to get rid of the clot, he sought to cause clotting, and at the same time avoid hæmorrhage, by compressing the artery on the proximal side. The attempt failed, presumably because of pain, and, when the next case came under his care, he substituted the ligature for compression.

The operation was done June 22, 1785, at the Hôtel Dieu in Paris. The patient was thirty years old; the aneurysm, of the popliteal artery, was as large as a turkey's egg. By an incision two inches long, Desault exposed the artery "immediately below the ring of the third adductor," separated it from the nerve, and tied it; he placed also a *ligature d'attente* above it, and tied this on the sixth day. The tumor promptly diminished to half its size, and the œdema of the leg disappeared. On the eighteenth day the ligature came away, and on the following day a large quantity of pus and blood escaped through the wound, apparently in consequence of rupture of the sac, and the wound then healed.

Desault operated upon only one additional case; this was shortly after Hunter's first case, and Desault, following Hunter's example, which was known to him, placed the ligature on the femoral artery, but at a still higher point. The patient died.

There remains now to be considered only the part taken by Hunter in the introduction of the ligature. We have already seen that in September, 1785, three months after Desault's operation, he had nothing to suggest in the treatment of a femoral aneurysm as large as a medium-sized orange, except compression of the artery in the groin, and that this was unsuccessfully tried. Three months later, December 12, 1785, he tied the femoral artery for a popliteal aneurysm.

The case was reported by Everard Home, in the "London Medical Journal," 1786, p. 394, and again, with four similar operations done by Hunter and three by others, in "The Transactions of a Society for the Improvement of Medical and Surgical Knowledge," London, 1793, p. 138. The date of the reading of the latter paper is not given, but that

of the one that precedes it is September, 1789, and that of the one that follows it is September, 1790. The second account is almost a literal transcript of the first. I quote from the second:

The patient was a coachman, forty-five years old, and the aneurysm "was so large as to distend the two hamstrings laterally and make a very considerable rising between them. . . . The operation was begun by making an incision on the anterior and inner part of the thigh rather below its middle, which incision was continued obliquely across the inner edge of the sartorius muscle, and made large, to give room for the better performing of whatever might be thought necessary in the course of the operation. The fascia which covers the artery was then laid bare about three inches in length, after which the artery was plainly felt. A slight incision, about an inch long, was then made through this fascia, along the side of the vessel, and the fascia dissected off; by this means the artery was exposed." A double ligature was passed around the artery [and vein] and "cut so as to form two separate ligatures. The artery was now tied by both these ligatures, but so slightly as only to compress the sides together. A similar application of ligature was made a little lower. The reason for having four ligatures was to compress such a length of artery as might make up for the want of tightness, it being wished to avoid great pressure on the vessel at any one part." [A fuller explanation of this practice is given in an earlier sentence (p. 145) as follows: "The cause of failure arises from tying a diseased artery, which is incapable of union, in the time necessary for the separating of the ligature." Apparently, Hunter thought that by tying the artery loosely more time would be given for the artery to become sealed before the ligature cut through. Certainly his intention was not simply to diminish the stream, for the ligatures cut through, and in his subsequent operations he used a single ligature and tied it tightly.] Secondary hæmorrhage occurred on the ninth day, but was controlled by a tourniquet; "on the fifteenth day some of the ligatures came away, followed by a small discharge of matter, the tumor in the ham being lessened." In April, and again in July, more of the ligatures came away, and on July 8, 1786, he was discharged cured. April 1, 1787, fifteen months after the operation, he died of remittent fever. His following four operations were similarly performed, except that in the fourth and fifth the artery alone, and not the vein, was tied. The second died of secondary hæmorrhage on the twenty-sixth day.

This is followed by the account of three operations performed after the same method by other surgeons, of one of which, by Pott, he says: "*This mode of operating*"* was adopted by Pott in a case of popliteal aneurysm," and he goes on to describe how the artery, probably the popliteal, was exposed by "an incision five inches in length, upon the posterior part of the thigh . . . between the two hamstrings"; and he adds (p. 173): "The mode of taking up the artery in the ham must be always unfavorable to the future success of the operation, if either the artery itself should be diseased, or if the tumor, by being so contiguous to the violence done in the operation, should be affected by

* "London Medical Journal," 1788, p. 149. "Cases of the Spontaneous Cure of Aneurysm," by Mr. Edward Ford.

* Italics mine.

the consequent inflammation, which seems to have been the case in Mr. Pott's operation, as I understand two abscesses were found close to the sides of the sac." Here is the same operation as that done by Desault (ligature of the popliteal artery) and quoted by Home, in the first authorized account of Hunter's method, as an example of Hunter's method, and this in itself would be sufficient, even if it were not corroborated again and again in the article, to show that Hunter's only idea was to tie the artery without opening the sac, and the reason he gives for tying it at a somewhat higher point (two inches at the most) than Desault and Pott did is ("London Medical Journal," and repeated by Home, *loc. cit.*, p. 146) that, "if the artery should afterward [after ligature of the popliteal] give way, there will not be a sufficient length of vessel remaining to allow of its being again secured in the ham. To follow the artery up through the insertion of the triceps muscle, to get at a portion of it where it is found [? sound], becomes a very disagreeable part of the operation; and to make an incision upon the fore part of the thigh, to get at and secure the femoral artery, would be breaking new ground—a thing to be avoided, if possible, in all operations." In one of the remaining two cases, a femoral aneurysm, extending to within two inches of Poupart's ligament, Mr. Cline tied the artery *half an inch below* the origin of the profunda, and, as the dissection showed, two inches above the orifice of the sac. This also is given in illustration of the method, and yet there could have been no collateral branches between the ligature and the sac; certainly none are mentioned.

In short, his one idea was to avoid secondary hæmorrhage by tying the artery at such a distance from the aneurysm that it would probably be found healthy, and to make the application of a second ligature easy if such hæmorrhage should occur. Of the "excogitation of a principle by profound reasoning," of which Mr. Holmes speaks, there is not a trace in this account; of the second "great merit" attributed to him by the same able writer, "that it was not necessary to stop the circulation through it [the sac] absolutely, but only," as he said, "to take off the force of the circulation," there is no justification except this quoted phrase, which, in view of the fact that the ligatures divided the artery completely, although, perhaps, more slowly than if they were tied tightly, certainly can not have the meaning attributed to it of only diminishing the stream of blood, and which, even if it did, was abandoned after the first operation, when he substituted a single ligature tied tightly for four ligatures tied loosely.

Moreover, the idea of curing an aneurysm by simply diminishing the flow of blood through it was by no means new; it underlay all the preceding attempts to cure by compression, and was plainly included in Desault's lecture reported by Assalini and quoted above. It was not until after the ligature in continuity had shown that the danger of secondary hæmorrhage was still present that very forcible compression, to effect complete and permanent closure of the artery, was tried as a substitute for the ligature.

The three grand merits claimed for Hunter (Holmes's "System of Surgery," art. "Aneurysm") are that he had

seen: 1. That it was not necessary to turn out the clots; 2. That it was not necessary to stop the circulation through the sac absolutely, and that, therefore, the artery might be tied at some distance above it; and, 3. That the ligature of the main artery would not involve gangrene of the limb. Now, of these, the first was certainly known by Desault, through a post-mortem examination, and probably by most other surgeons, as is proved by their attempts to cure by compression. As regards the second, the fact contained in the first clause, that it was not necessary to stop the circulation completely, had been long known before his operation; and the inference stated in the second clause was not drawn by Hunter, and was not given as his reason or justification for placing the ligature at a higher point. Home's paper (which, it must be remembered, is an official one, and made in Hunter's name) does not contain a single reference to collateral branches given off between the ligature and the aneurysm.* The phrase "that simply taking off the force of the circulation is sufficient," which is also quoted as meaning that a diminished stream of blood was expected to be brought to the aneurysm by collaterals, is the only thing in the entire paper that can suggest such an idea; and that neither this meaning nor the one above referred to—of only partly compressing the artery—was intended to be conveyed by it, is shown not only by actual statement of the reasons and objects of the operation, but also by a case which he quotes (p. 156) in illustration of his argument—a case of spontaneous cure of an aneurysm by inflammation of the sac, accompanied by arrest of pulsation in the sac and in the artery immediately above it. If the phrase were written out in full to express the entire idea, it would read: "It is sufficient simply to take off the distending force of the arterial stream from the blood contained within the aneurysm; the blood will then coagulate in the sac and in the adjoining part of the artery, and the progress of the disease will be stopped; it is not necessary to open the sac."† The opening of the sac is what he was thinking of when he used the word "simply," not of the presence or absence of collateral branches, not of merely diminishing the stream.

* The only reference to collaterals in the first paper is one (p. 399) to the effect that "surgeons have laid too much stress on the necessity of large collateral branches being present to insure the success of this operation, . . . since we find that the trunk of the femoral artery may be taken up in any part of the thigh without producing mortification of the limb."

† Compare the corresponding paragraph in "London Medical Journal," letter of Home, November, 1876, p. 393.

"From these considerations [those quoted above about the desirability of not breaking new ground], suggested by the accident of the artery giving way, which happened several times to Mr. Hunter, he proposed, in performing this operation, that the artery should be taken up at some distance from the diseased part, so as to diminish the risk of hæmorrhage and admit of the artery being more readily secured, should any such accident happen. The force of the circulation being thus taken off from the aneurysmal sac, the cause of the disease would, in Mr. Hunter's opinion, be removed; and he thought it highly probable that, if the parts were left to themselves, the sac, with the coagulated blood contained in it, might be absorbed, and the whole of the tumor removed by the actions of the animal economy, which would consequently render any opening into the sac unnecessary." [Italics mine.]

The third great merit—that Hunter saw that the ligation of the main artery would not involve gangrene of the limb—had been known for a hundred years, and had been proved by every successful case in which the old operation had been used, and also by Desault's ligation in continuity six months before.

Both Desault and Hunter had the same object in view: to cure the aneurysm without opening the sac. Desault had a small aneurysm, and tied the popliteal at its upper end. Hunter had a large one, and tied the artery a little higher up (he could not well have done differently). Desault, in his second operation, went still higher, and tied a little below the apex of Scarpa's triangle; subsequent operators have habitually tied in the triangle itself. Even the observation claimed for Hunter—that the artery was diseased above the aneurysm, and that this was the cause of the secondary hæmorrhage—had been made before him, and was given by Pott as a reason for preferring amputation to the old operation (Pott, *loc. cit.*, p. 220).

I see nothing in Hunter's operation radically to differentiate it from Desault's and to justify the ascription of the method to the English surgeon. It seems to me to be beyond question that Desault had grasped the principle, and the difference of an inch, or two or three or six inches, in the distance, is a matter of detail which is to-day subordinated to the rule that the artery should be tied at the nearest accessible point that does not directly involve injury to the sac.*

Why Hunter's name should have become so pre-eminently identified with it is to be explained by reasons entirely independent of the principle involved, and of the measure in which that principle was grasped by the two great rivals. Hunter enjoyed a great authority and was widely known; his example was followed, his practice was quoted by those who wrote in our language. Desault lived and made his great discovery at a time when his nation was entering upon a revolution that shook the world and isolated France by war for nearly twenty-five years; he made it at a time when men were occupied with mighty interests beside which the advances of science seemed as nothing; at a time when, to Lavoisier pleading for another fortnight of life that he might complete certain experiments, the answer was: "The Republic has no need of such." What wonder that at such a time and amid such surroundings his discovery should have passed unheeded by those about him, and have remained unknown by those who were at war with his country? It is our privilege, our duty, to recognize his work and to give him the credit that is his due.

* It seems unnecessary, in view of these facts, to consider the question, whether or not Hunter knew of Desault's operation before performing his own. The facts bearing upon it are, that Assalini was at Desault's operation, afterward went to London, and was present at Hunter's operation, and that Hunter, three months before his operation, seems to have made no suggestion of this treatment in the case of femoral aneurysm, quoted above, which he saw in consultation, and which, after a futile attempt at cure by compression, was abandoned to its fate.

ANTISEPTICS IN MIDWIFERY.*

By CHARLES JEWETT, M. D., BROOKLYN,

PROFESSOR OF OBSTETRICS AND DISEASES OF CHILDREN IN THE LONG ISLAND COLLEGE HOSPITAL.

ANTISEPTIC measures for prophylaxis in childbed may be divided into two classes:

1. Those addressed to the surroundings of the patient.
2. Those applied directly to the parturient canal during labor and the puerperal period.

The former aim to protect the patient by an aseptic environment.

The latter assume to destroy or disarm septic matter that may have gained lodgment in the genital tract.

While the importance of the one class of procedures must be generally conceded, opinion and practice are by no means uniform in respect to the other.

Though for many years fully committed to their use, the recent experience of the writer has led him to abandon prophylactic injections as a routine practice in the puerperal period, and to place little dependence on them during labor. On the introduction of antiseptics into the Maternity service of the Long Island College Hospital, a marked improvement was at once apparent in the temperature charts. A normal thermometric line became the rule where it had formerly been the exception. Nearly sixty-three per cent. of the women confined in the year following the adoption of antiseptic precautions had normal temperatures during the post-partum week, while not more than sixteen per cent. had wholly escaped febrile temperatures before.

Early in 1883 I began a series of observations with a view to determine whether this improvement was due in any degree to the use of antiseptic injections during the puerperium. The result has already been in part reported.

Two parallel series of hospital cases were treated side by side, one with and the other without vaginal injections. Both series numbered twenty-nine patients—sixteen in the douched and thirteen in the non-douched class. The principal disinfectant was a 1-to-1,000 bichloride solution, a 3-to-5-per-cent. carbolic solution being used in a few cases only. The injections were administered by competent nurses, and it is fair to presume that they were managed with care and skill. They were repeated twice daily during the post-partum week. Of the sixteen douched cases, eleven had temperatures that did not exceed 99° 5' F. in the first puerperal week. Of the thirteen non-douched cases, the temperature record was constantly below 99° 5' F. in twelve. The morbidity was less in the patients left undisturbed by the douche. True, the departure from the normal was not necessarily always due to sepsis. Moreover, two operative cases were included in the douched series, while there were none in the other. While the result of these observations may not therefore be considered conclusive, especially in so small a number of cases, if it does not amount to an indictment of the puerperal douche, it certainly proves nothing in its favor.

The advantage obviously gained by the introduction of

* Read before the Medical Society of the County of Kings September 16, 1884.

antiseptics was clearly due to other measures than the douche. Routine injections of the genital tract during the puerperium were therefore abandoned as a useless if not injurious practice.

Local antiseptic measures for prophylaxis were subsequently confined mainly to the labor period. Vaginal disinfection was practiced at the beginning and close of labor, and, in case of prolonged or instrumental delivery, was once or twice repeated in the course of its progress. This method was believed to be in keeping with antiseptic principles as applied in surgical practice. The field of the obstetric wounds was cleansed before solutions of continuity occurred. After labor the wounds were treated with the disinfectant while still fresh, and were then left wholly at rest.

Further experience, however, has somewhat shaken my confidence in the value of even this practice. The reasons will best appear by relating the history of three cases of puerperal fever which befell the service during the last year.

I should state that the Maternity is located in the hospital building, from which, however, it is about to be removed. Yet the very disadvantage of the surroundings has afforded the better opportunity to test the value of local antiseptics.

In the latter part of December, 1883, erysipelas appeared in the general hospital service. A few days later a patient was attacked with childbed fever in the Maternity. The notes of this case are as follows:

J. S., aged twenty-three, married, primipara, in excellent health, was brought to the hospital in the ambulance, December 26th, after being fourteen hours in labor. First stage complete on admission. Four hours later—at 2 p. m.—was delivered of a female child, weighing eight and a half pounds. Labor strictly normal; sustained a slight laceration of the perineum. The vagina was thoroughly irrigated with the bichloride solution at the beginning and close of labor, and a forty-grain pessary of iodoform was placed against the cervix after each douche.

The perineal wound was dusted with iodoform on its occurrence, and was treated with immediate suture. Vagina and wound were thoroughly irrigated again with the bichloride solution immediately before and after the suturing. Ordered extract. ergot. fluid., ℥ xv, t. i. d. Douche to be continued twice daily. In less than twenty-four hours after delivery the patient complained of great hypogastric pain and tenderness, and the temperature rapidly rose to 103.75°. The subsequent course of this case was typical of an extremely painful diffuse peritonitis. Lochia at no time offensive. The vaginal injection was repeated every four hours from the invasion of the fever, without affecting the temperature. A single intra-uterine douche within twelve hours after the fever began was equally without effect, and was therefore not repeated. It may be of interest to note that the daily dose of opium reached a maximum of one hundred and eighty-eight grains. The patient died January 1, 1884. Autopsy revealed general peritonitis; no evidence of septic matter in the uterine cavity.

On the occurrence of infection the obstetric service was in part suspended. The fever patient was quarantined in a remote portion of the building. The Maternity was disinfected and placed in charge of an externe appointed temporarily for obstetric duty only, the resident staff withdrawing for the time from the lying-in service. Three

normal cases followed in course of the next six weeks. By mischance the next patient—confined February 7th—was attended by a member of the house staff. She developed childbed fever within forty-eight hours after labor. The following notes are taken from the hospital record of this case:

H. P., aged twenty-eight, single, primipara, of robust appearance, brought into the hospital, near the completion of the second stage of labor, February 7, 1884. Labor in all respects normal, lasting less than ten hours. No perineal wounds nor other notable injury to the passages. Child a female, weighing six pounds and a half. Bichloride vaginal douche, followed with iodoform pencil at the close of labor. Ordered a forty-grain pencil of iodoform placed against the cervix twice daily. On the evening of the 8th, during a temporary absence of her nurse, the patient left her bed and walked barefooted across the ward. Two hours later she was seized with a violent chill. Temperature rose rapidly, reaching 105.5° on the 9th. Lochia became extremely offensive.

The prominent feature of this case was high temperature, with slight oscillations ranging from 103.6° to 105.5°. Pain was almost wholly absent, and there was intolerance of opium, small doses at long intervals inducing deep somnolence. Vaginal injections of the sublimated solution were given every four hours, and, this failing to bring down the temperature, two intra-uterine injections of the same solution were administered, also without effect. The patient died on the 12th. On autopsy, the prominent lesion found was general peritonitis, with accumulation of pus in the pelvic cavity. Uterine cavity healthy, and involution nearly normal for the time.

This patient had been promptly isolated on the occurrence of fever, the wards and beds disinfected, and the department placed in the care of an entirely new corps of attendants. Seven confinements followed with substantially normal post-partum histories. A third case of metria then occurred in a patient delivered April 22d. The attending personnel in this instance were free from all suspicion of septic contamination.

The following extracts from the hospital notes present the salient facts of the case:

M. B., aged twenty-two, primipara, somewhat anæmic. Admitted April 10th. Delivered at 9 p. m., April 22d, of a female child, weighing six pounds and a half, after a natural labor of about eighteen hours' duration. This patient sustained a laceration of the perineum extending half way to the sphincter ani. At the beginning and close of labor the same methods of local disinfection were practiced in this as in the first case; no puerperal douche was used till the fever developed. The perineal wound was dusted with iodoform and sutured. Nothing abnormal occurred till the evening of the 24th, thirty-six hours after labor, when the temperature began to rise. A slight chill followed on the morning of the 25th, the thermometer then registering 104.5°. There were no subsequent rigors. The lochia were at no time offensive, nor was there any pelvic pain or tenderness during the history of the case, except in the perineal wound. The sutures were removed on the fifth day. The perineum was very tender on pressure; union imperfect; wound subsequently reopened throughout. On the 27th, patient had several stools, largely of a bloody, mucous character, attended with tormina and tenesmus. This dysenteric attack was once or twice repeated in the succeeding few days. Occasional though not troublesome vomiting from this date. On the 29th

and on the 30th of April the temperature fell to 100° F. May 1st it went rapidly up to 104.5°, and, on the 2d, the perineal wound, the vestibule, vagina, and vaginal portion of the cervix were found covered with a thick, fibrinous exudate. At this time a small, superficial phlegmon appeared on the extensor surface of each forearm, and there was more or less tenderness and stiffness of the knee- and wrist-joints. The mind remained clear till within two or three days of death, low, muttering delirium then supervening. A notable feature of this case, too, was intolerance of opium. A single dose of tr. opii dead., ℥ viii, on May 6th, induced marked somnolence. At about this time the patient showed signs of intoxication on increasing the dose of whisky from one to two drachms hourly. Died May 7th.

On the invasion of the fever the sublimated vaginal douche had been ordered every four hours, each douche to be followed with a forty-grain pessary of iodoform placed against the cervix. The vaginal douche failing to affect the temperature after a few hours, a single intra-uterine injection was given. As the result was wholly negative, the latter injection was not repeated. The vaginal disinfection was discontinued May 2d and 3d, and repeated at intervals of two hours thereafter.

In proof of the thoroughness with which the sublimated injections were used, I may state that, in addition to the usual local erythema, the patient, during the last few days of her life, developed symptoms of slight mercurial poisoning.

Referring to the admirable paper recently presented to the society by Dr. Thallon on the use of "Mercuric Bichloride in the Treatment of Diphtheria," it will be of interest to note before leaving this case that the vaginal exudate developed and grew space on a mucous membrane almost constantly bathed in a 1-to-1,000 bichloride solution.

The treatment other than antiseptic has been omitted, as it has no interest in connection with the present object.

As will be inferred from the history, the last case was one of pyæmia. On autopsy, minute abscesses were found in the kidneys and spleen, and large ulcerated patches on the mucous surface of the colon near its cæcal end. Peritoneum healthy. Uterine involution normal for the period. A fibroid of the size of a walnut was found in the anterior wall of the uterus nearly under the peritoneum, and behind the fibroid was a cavity containing ichorous, foul-smelling pus. Vaginal false membrane as above described.

To recapitulate the facts bearing on the present question, the sublimated vaginal injection was given in two of the cases at the beginning, and in all at the close of labor. After each injection from forty to eighty grains of iodoform were deposited in the vagina. The perineal wounds were sprinkled with iodoform, were a second time irrigated with the bichloride solution, and were closed with sublimated silk sutures. In a word, in each case the infection occurred despite a carefully ordered vaginal disinfection.

I have therefore been compelled, though reluctantly, to relax my faith in the protective power of local antiseptic measures in the parturient as well as the puerperal patient. They can not be relied on to procure immunity from infection in the presence of septic surroundings. They must not be trusted to remedy the sins or the accidents of uncleanness. An experience such as I have recited goes to emphasize the importance of an aseptic rather than antiseptic management of the patient. The avoidance of infection, as some writer has expressed it, is a better reliance than disinfection. And it is to aid in accomplishing this end, by

promoting a cleanly environment, that antiseptics are most valuable in obstetric prophylaxis.

With reference to the use of utero-vaginal injections as a therapeutic resource, the foregoing cases are also instructive. Much as I value the measure, and brilliant as its results often are, there is, I am persuaded, a class of cases which are not at any stage amenable to this method of treatment.

NORMAL PARTURITION ALWAYS PHYSIOLOGICAL.*

By ERNEST PALMER, M.D.,

BROOKLYN.

MR. PRESIDENT AND GENTLEMEN: Fully appreciating my inability to add anything new at this time to the practice of obstetrics, and with the knowledge that the profession at large have so recently been entertained with the advanced views upon midwifery practice, I have deemed it advisable to make a retrograde step, so to speak, and look a little into the physiology of normal parturition, convinced as I am in my own mind that in the hurry for improvement, so called, in this branch of practice, the truly physiological condition has for the time being been lost sight of and a pathological one substituted.

This, at least, is the interpretation I have arrived at after a somewhat careful study of the writings of the advanced school of obstetricians, and that we are no longer to look upon gestation as a purely physiological process, completed by gradual but well-defined stages of development and elaboration of normal tissues, but as a more or less pathological condition, due to the changes which take place in some of the fluids and solids of the pregnant woman, which nature finds it necessary to alter in quality and quantity to meet the requirements of the developing embryo.

I fail to see the slightest analogy between normal parturition and any condition to be met with in the whole range of medicine or surgery; for, while in normal pregnancy there is simply a reproduction of normal structures terminating in the production of a new being which is itself physiological, in medicine and surgery we are at once in the presence of every manner of deviation from the normal or physiological in the treatment of deformity, injury, or disease. Losing sight for the time being of these facts, I believe, led to the inauguration of the ante- and post-partum treatment of the lying-in woman with which all are now familiar, and which therefore need not be repeated here in detail; but, the groundwork of this treatment being the antiseptic vaginal douching and medication, it will aid me in illustrating the physiological points of my paper.

Leishman, in his "System of Midwifery," in describing the phenomena of labor, says: "From an early stage of labor the tissues are prepared for their new function by a profuse secretion from the vagina and cervix of a thick, colorless mucus, while the parts from which it flows become softer and more cushiony. This discharge, which is occasionally tinged with blood, is frequently mixed with little semi-solid albuminous masses, and is very obviously provided by nature

* Read before the Medical Society of the County of Kings, September 16, 1884.

for the purpose of lubricating the parts, and thus facilitating the progress of the fetus along the canal through which it has to pass. Upon the *quantity* of the secretion the ease of the labor undoubtedly depends *in no small degree*, not by its lubricating action alone, but because its appearance involves a softening and general preparedness of the tissues dependent upon the unloading of the congested vessels. There is *no sign* upon which, as indicating the probable duration of a case of labor, the accoucheur looks with more confidence than this; and, from a copious secretion and relaxed condition of the parts, he augurs an easy and speedy labor, while from a dry, constricted, and rigid vagina he learns that, in all probability, a lingering and exhausting labor will lead to a tardy delivery."

Here we have described at some length the physiological function of the cervical and vaginal secretions, and the very important part they perform during the act of parturition, as well as the value to be attached to the presence of a free secretion in the vagina, in aiding delivery, brought into strong contrast with what may be expected when there is a diminution in the amount, and yet, with a full knowledge of their importance, we are directed by the antiseptic midwife, by frequent syringing of the vagina during the first stage of labor, to wash away these secretions, upon the bare presumption that they may possibly prove a source of septic danger to the mother.

In other words, removing an important physiological factor from a normal delivery to prevent a possible pathological complication.

Labor being completed under the antiseptic method of prophylactic vaginal douching and medication with iodoform, it is at once resorted to, to combat the much-dreaded lochia being absorbed through the denuded uterine muscular tissue or slightly lacerated mucous membrane of the vagina.

Here, again, the stamp of pathology is placed upon a physiological retrograde metamorphosis inaugurated immediately after labor.

Professor Thomas, in his monograph upon the prevention and treatment of puerperal fever, says:

"The uterus, about the two hundred and eightieth day of gestation, contracts and expels the child, then the placenta and membranes, and then closes its empty cavity and rests.

"Let us suppose that in forty-eight hours after delivery a primipara dies of pneumonia, and we are allowed to lay open the genital tract and examine it from the fundus uteri downward.

"Outside all looks well; the uterus is merely much larger than in the non-pregnant state.

"Within, it presents a very different appearance; the whole endometrium, covered over by the grayish, sloughy-looking decidua vera, presents all over its surface an unhealthy, unclean, and diphtheritic look, although free from exudation. Here and there shreds of membrane consisting of small portions of the decidua reflexa, which has become adherent, appear, partially detached and somewhat decomposed.

"At one point the large placental site is seen, raw,

irregular, and covered over by minute traces of the placenta and small blood-clots which close the mouth of the uterine sinuses.

"The odor of the opened uterine cavity, the walls of which are thus covered, is disagreeable. The substances mentioned have for forty-eight hours been dislodging themselves, and, mingling with the pinkish fluid which pours like an unhealthy sweat from the placental site, constitute what is called the cleansing or lochial discharge."

Certainly Professor Thomas does not expect us to accept this examination of the uterus, vagina, and lochia of a woman dead from pneumonia, for what really exists in the parts after a purely normal delivery, but, bringing it forth as he does to elucidate one of his reasons for prophylactic treatment in all midwifery cases, I have concluded he infers that the same condition is present after a normal case. In the first place, we might reasonably object to the subject upon whom he made his observations. It is hardly possible that the uterus of a woman dying from pneumonia forty-eight hours after delivery would present the typical post-partum physiological appearances of the uterus; but I will show farther on that what he presents as pathological is simply natural and protective, not pathological or inclined to be destructive, as comparison with the following clearly shows. Professor Dalton, in his article on "Reproduction," Dalton's "Physiology," page 664, in describing the regeneration of the uterus after delivery, says: "A remarkable phenomenon connected with the renovation of the uterine tissue is the appearance in the uterus during pregnancy of a *new mucous membrane* underneath the old, and destined to take the place of the latter after its discharge. If the uterus be examined immediately after parturition, it will be seen that at the spot where the placenta was attached every trace of mucous membrane has disappeared.

"The muscular fibers in this situation are exposed, and the mouths of the ruptured uterine sinuses are also visible, their thin edges hanging into the cavity of the uterus, and their orifices plugged with bloody coagula. Over the rest of the uterine surface the decidua vera has also disappeared.

"Here, however, notwithstanding the loss of the original mucous membrane, the muscular fibers are covered with a semi-transparent film of a whitish color and soft consistence. This film is an imperfect *mucous membrane of new formation*, which begins to be produced underneath the decidua vera as early as the beginning of the eighth month.

"The mucous membrane of the cervix, which takes no part in the formation of the decidua vera, is not thrown off in parturition."

The lochial discharge receives but meager description at the hands of physiologists, they by courtesy delegating to obstetrical authors the right to more fully present the subject in its direct relation to midwifery practice, and to Leishman we are indebted for the most complete and yet concise description of its origin, course, composition, and physiological function.

Leishman says: "In order to understand the true nature of the lochial discharge it is necessary to consider for a moment the anatomical condition of the parts from which it springs.

"That part of the uterus from which the placenta has been separated was compared by Harvey to the stump of a limb after amputation; but, although the simile has been frequently repeated, physiologists are well aware that it is only to a limited extent correct. The vessels, no doubt, are torn across in the course of the separation of the placenta, but, *with this exception, there is no real breach of tissue, as nature has for many weeks been preparing for the process of separation.* At birth the inter-utero-placental tissue divides into two layers, as was formerly explained, one of these remaining adherent to the uterine wall, along with portions of the decidua serotina. If the womb be examined shortly after delivery, that part of it to which the placenta was attached will be observed to be thicker than the other portions, and projecting somewhat into the cavity of the uterus.

"Upon the surface, which is rugged and unequal, small clots, projecting from the orifices of the closed vessels, and so contributing to their efficient closure, are observed along with shreds of membrane; and over the whole inner surface of the cavity of the organ remains of the decidua vera or of the subjacent textures, from which it has been stripped, are clearly to be made out. The discharge, then, which constitutes the lochia is, in the first instance, composed almost of pure blood."

Farther on the same author says: "The lochial discharge has a peculiar odor, sometimes offensive in character, but at no time, if it follows a normal course, is there a purulent discharge, nor is the process in *any way analogous to the suppuration which accompanies the reparative process of a healing stump.*"

Other obstetrical authors devote but little time and space to the description of the lochial discharge, but generally accept it to be due to retrogression, atrophy, and fatty degeneration of the muscular tissue of the uterus, mixed with shreds of decidua, etc.; and one writer (Tyler Smith) goes so far as to say, in his "Lectures on Obstetrics": "I look upon the exfoliative shedding of the mucous membrane or uterine decidua as in many respects analogous to the change which takes place in the uterine mucous membrane at the catamenial periods, and the lochia and menstrual discharges appear to be essentially the same, except that the lochial fluid is more profuse than the menstrual."

Much more might be said regarding the physiological conditions of parturition, but I believe it will be accepted by my auditors as a fact, that uncomplicated labor is a purely physiological act, for which ample preparation has been made in the system to provide for the increased demand made upon it, and to guard against all the ordinary incidents pertaining to that function. The excess of the fibrin in the blood of the pregnant woman is designed by nature to perform some important duty yet imperfectly understood by physiologists, although many hypothetical theories as to its function have been advanced, and await verification, but nothing, so far as I can find, has been suggested as to the probability that the increased fibrin in the blood of pregnancy may be an important factor in the elimination of effete material from the fœtus, by and through the circulatory system of the mother. This theory seems

quite as plausible as any offered in explanation of the physiological deterioration of the blood in pregnancy, and, I think, is worthy of further investigation.

Nature's hæmostatic is by the coagulation of the blood, and, as it is upon the presence of fibrin in blood that coagulation depends, it seems as though the hyperinosis of pregnancy through the augmented fibrin promoted rapid coagulation of the blood at the mouth of the uterine sinuses and checked undue hæmorrhage after the placental delivery.

Nature, in her all-wise provisions for the reproduction of her species, has, with regard to the human uterus, taken timely steps to insure the integrity of the generative tract after delivery.

By referring to the quotation just made from Dalton's "Physiology," we find that, so early as the commencement of the eighth month of gestation, a new mucous membrane has already been formed in the cavity of the uterus, covering and protecting it, except at the site of the placental attachment, while at this point the denuded tissue is covered with a semi-transparent film of soft consistence. To add greater protection to this part, the inter-utero-placental tissue divides into two layers at birth, one of these remaining adherent to the uterine wall, along with portions of the serotina, as already described by Leishman.

Here are two anatomical structures purposely designed to give protection to the cavity of the uterus, and whose presence our antiseptic brethren seem to ignore or be in ignorance of when describing the dangers of septic absorption through the *denuded* muscular tissue of the womb, a condition which really does not exist in the uterus at any time during parturition.

Sufficient description has been given of the lochial discharge to show that to compare it with a fluid composed of "dead and decaying tissue" is not tenable, not being founded upon well-established physiological data; and no pathologist has so far had the temerity to include it in his index of pathological fluids, where it should certainly be found if composed of morbid tissue.

Agreeing with Tyler Smith in his analogy between the lochial and the menstrual flow, I am confident that the dangers arising from it are more imaginary than real; and that in puerperal septicæmia it is simply one factor, and not the primary cause of the disease.

So far as the liability of communication through the physician, nurse, or surroundings of the patient is concerned, no reasonable person will doubt; but it does not follow that we are to look upon the uterus of the normal patient as a mine in which all sorts of poisons may be generated, to explode at any time.

From the very fact that everything pertaining to the reproductive organs, post partum, is absolutely physiological, the moment we begin to look upon it as a pathological state we are in great danger of interrupting or inhibiting physiological processes by our therapeutic agents designed to prevent possible pathological complications; and the question naturally arises, whether ante-partum syringing of the vagina does not thwart nature's means of lubricating the vagina for the passage of the child by removing the secretions upon the presumption that it may contain a

nidus of bacteria which will propagate in the after-coming fluid.

And here let me enter my firm protest against the antiseptic method of conducting normal midwifery cases, upon the ground of its being established upon misconceived theories of pathology, and in direct violation of the physiological laws of reproduction. I condemn it as being unnatural and irrational, and, failing to see the utility of the method, can readily appreciate the dangers that would arise from its universal adoption; and I believe that, at a time not far distant, the pendulum regulating obstetrical practice, now so far over on the side of antiseptics, will swing back and vibrate within the bounds of its physiological sphere.

In conclusion, let me, in the language of Professor Bedford, "urge upon you a profound respect for Nature; her temple is the proper place for the student of midwifery; there it is that she discourses most eloquently, though silently, and the best obstetricians will be those who have worshiped most zealously at her shrine," and I am convinced that your conversion will lead you to believe that normal parturition is always physiological.

A METHOD OF RELIEVING ASPHYXIA FROM BLOOD IN THE TRACHEA.

By H. H. A. BEACH, M. D.,
BOSTON.

ASPHYXIA from blood in the trachea is an accident to which the best surgeon is liable in operations involving the mouth, larynx, trachea, and their vicinity, unless the head-suspension method of Rose, which is impracticable in some instances, is employed. This often alarming emergency may be met promptly and effectively by an expedient that, so far as I can ascertain, originated with Dr. Henry J. Bigelow. As his house-pupil at the Massachusetts General Hospital, in the year 1867, I had the opportunity of witnessing the first application of his method, in assisting at the operation where it was employed.

The patient was a woman, with a tumor of the upper jaw, who entered the hospital June 19, 1867, and the operation was performed publicly on the same day, before the hospital staff, a large number of practitioners, and the medical class of Harvard University, in the old operating theatre of the hospital, where the first public demonstration of *anæsthesia* by sulphuric ether was made. It was afterward commented on by Dr. Bigelow in the operating theatre as the *key* to success in the treatment of this emergency. The following transcript from the hospital records, then written by myself (vol. 129, p. 159), may have some interest for the profession:

"Patient, thirty-nine years old, enters hospital with a tumor of left side of face, extending over a space of about two inches in diameter, being adherent to the facial and zygomatic surfaces and malar process of the superior maxillary and the inner surface of the malar bone. It protrudes one half of an inch beyond the zygomatic process of the malar bone, extends into the antrum, is elastic, has a uniform surface, and of late has grown rapidly. One year and a half ago a tumor was removed from the facial surface of the superior maxilla of that side.

"*Operation.*—Dr. Bigelow made a semilunar incision of five inches, from the commissure of the lips to the middle of the space between the eye and the ear; a straight one from the septum of the nose through the upper lip, and dissected up the flap to the border of the orbit. At this point respiration stopped; the surface of the body and extremities became livid and cold, although the hæmorrhage was inconsiderable and she was not inhaling ether. The head was immediately lowered, the feet were elevated, and the patient, who had not respired for eight or ten seconds, during which the pulse had continued to beat, was suddenly found to be pulseless. The operation was stopped, and the usual efforts were made to induce her to breathe. A catheter was passed into the trachea by the mouth, through which air was blown unsuccessfully. Two or more minutes had now elapsed without pulse or respiration, the operator expecting, as not infrequently happens, a full respiration with some gurgling from collected blood; but it was now evident that no time was to be lost. Dr. Bigelow opened the trachea with one stroke of the scalpel, and then with his mouth sucked a certain amount of liquid blood from the trachea, at the same time inflating the lungs by passing the catheter down the trachea through the opening *beyond the point of obstruction*; galvanism was then most thoroughly applied to the cardiac region, but it was only after the lapse of what seemed to be from five to eight minutes that the first inspiration took place. During five minutes more the patient was unable to breathe without inflation, after which her breathing was good and the pulse returned. Both increased in strength and frequency until it was thought best, after consultation with Dr. J. Mason Warren, Dr. Clark, Dr. Cabot, Dr. George H. Gay, and Dr. Hodges, to continue the operation and remove the diseased mass. The zygomatic arch, the external angle of the orbit, the palatine arch between the second incisor and canine teeth, and the nasal process of the superior maxilla, were successively divided by a bone-forceps. Upon prying the jaw down from its attachments, it crushed like an egg-shell, having become thinned by absorption. The débris were removed together with the tumor, which was lobulated, friable, and very vascular. General oozing was checked by sponges dipped in liquor ferri subsulphatis. Six vessels required the ligature. Wound closed with sutures."

The value of this use of the elastic catheter in expelling blood-clot was so evident in the case just described that the hospital tracheotomy case has from that time been supplied with one for this especial purpose, and it has been a common practice of the surgeons to carry a catheter in going to a case requiring tracheotomy. In the "Boston Medical and Surgical Journal" for December 14, 1882, Dr. M. H. Richardson calls attention to this subject in an able article entitled "Tracheotomy, with a Report of Three Cases." Dr. Richardson informs me that the idea of employing the catheter, as described, was derived from the teaching of Professor Bigelow. In the discussion which followed the reading of Dr. Richardson's paper before the Boston Society for Medical Observation, Dr. Porter, Dr. Gay, Dr. Richardson, and Dr. Bolles dwelt upon the advantages which an elastic catheter thus introduced offers. Following that discussion, Dr. George W. Gay read an interesting paper on "Tracheotomy in Croup" before the American Surgical Association, at Washington, D. C., on May 2, 1884, that was published in the "Medical News" for July 12, 1884. His experience was, like that of Dr. Bigelow, in a case of sudden and great emergency. Dr. Gay has kindly furnished me with the notes of this case, which occurred at the City Hospital,

March 30, 1882. The vertebral artery and vein had been wounded in a gunshot injury, and the hæmorrhage into the pharynx and trachea was from a hidden source, a direct communication existing between the pharynx and the wounded vessels. The pharynx was flooded with blood, and through the larynx the trachea soon became blocked. This occurred whenever the patient was turned on his side or face—a position necessary to afford an examination of the wound or permit the extraction of the ball. Dr. Gay met this emergency promptly and successfully by tracheotomy and the catheter. This had never occurred to him before, and was then suggested by the alarming condition of his patient, who lived one week after his resuscitation without a recurrence of the hæmorrhage. He died of pleurisy and pericarditis, as shown by the post-mortem examination, which also disclosed the comminution of the transverse processes of vertebræ in the wound, the wound of the vertebral artery and vein, and their communication with the pharynx and larynx.

The essential point in the manœuvre is to push the end of the catheter beyond the point where the clot obstructs the trachea, so that the air forced through the catheter may expel the clot by driving it upward. Should the pressure be insufficient to clear the trachea, it may be aided by compressing the chest, as suggested by Dr. Bigelow.

A CASE OF FOREIGN BODY IN THE BRONCHUS.*

By JOHN A. WYETH, M. D.,

PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC.

ON September 7, 1884, Albert Austin, aged twelve years, residing at Wallingford, Conn., while in the act of projecting a pin-dart from a blow-gun, made a sudden inspiratory effort, and carried the missile backward into the trachea.

According to the statement of his mother, a woman of great courage and presence of mind, as I have reason to know, he coughed violently, gasped for breath, turned blue in the face, and for a few minutes seemed on the point of suffocation. Fortunately, these symptoms disappeared, and the boy only suffered from a slight cough. The mother gave him a tumblerful of warm salt water, but this did not make him vomit until after the symptoms of asphyxia had disappeared.

He was seen by the family physician, Dr. J. D. McGaughey, who, after careful examination, located the body in the bronchus, and ordered the patient to be kept quiet. The boy was seen by a number of physicians within the next three days, in Wallingford and New Haven, and, on the 11th of September, he was brought to this city and referred to me, by the courtesy of my friend, Dr. E. H. Grandin.

On that day he was examined by Professors Leaming and Elsberg and myself, with Dr. McGaughey. The physical signs pointed to its lodgment in the right bronchus be-

yond the first bifurcation. At this point there was a hissing, fluttering sound in both respiratory acts. In the anterior portion of the right lung the respiratory murmur was diminished. On the left side the vesicular murmur was normal.

Professor Elsberg, after a careful laryngoscopic examination, located the foreign body in this bronchus. Professor Leaming, Dr. McGaughey, and I concurred in the diagnosis. On the next day, acting with the advice and in the presence of these gentlemen and the house staff at Mt. Sinai Hospital, I performed tracheotomy at the lowest available point.

I introduced my little finger downward as far as it would reach, and upward to the glottis, without feeling the dart. With the patient on his back, his head hanging over the edge of the table, I then introduced a long, delicate trachea-forceps down to the bifurcation and off into the right bronchus. The jaws were then slowly opened and advanced a quarter of an inch, closed, and withdrawn, in order to see if I had grasped the pin. This manœuvre was repeated on every face of the bronchial circumference, and in its length.

Assured, from the careful search, that it was beyond the reach of the forceps, at the suggestion of Professor Leaming, I introduced a loop of silver wire, hoping that it would pass into the subdivision of the bronchus in which the dart was lodged. This repeatedly proved futile, and, feeling that I had made every justifiable effort, the operation was ended by passing silk sutures through two of the divided rings of the trachea and stitching these to the integument on either side of the wound. The strings were tied to adhesive strips, and these applied so that the trachea was kept wide open.

The patient recovered without any accident or marked exacerbation of temperature. He coughed and expectorated bloody mucus in small quantities for two or three days.

On September 24th Professors Jacobi, Janeway, and Ripley, at my solicitation, examined the patient. The first two gentlemen named could not, from the physical signs elicited, locate the missile, or feel assured that it was in the respiratory tract. Dr. Ripley held that it was in the left lung, believing that it had shifted from one bronchus to the other. It was deemed advisable, as a result of this consul-

tation, to keep the tracheal wound open, in the hope that, if the pin became loosened, it might be ejected without lodging in the larynx, and, in order to do this safely, I determined to introduce a silver cannulated tube.

* Presented before the New York Pathological Society, October 22, 1884.

When I anæsthetized the patient on the following morning, September 25th, I determined also to again search for the dart, having had made an instrument for this especial purpose.

The boy was placed on his right side, with the head hanging down, so that the blood would flow into the mouth or out of the wound, which bled considerably from the granulation-tissue broken up by the exploration. While in this position I introduced my finger well down the trachea, searching for the dart. The patient became blue from the arrest of respiration, and when I withdrew my finger he inspired deeply, and followed this with a violent and prolonged expiratory effort, in which I placed my thumb in and occluded the tracheal wound. I again introduced my finger with the same result, and, after this, introduced the trachea-tube. At this juncture the patient, being only partially anæsthetized, made some spasmodic movements of the muscles of the throat, and seemed again threatened with asphyxia to such an extent that I removed the tube from the trachea. At this moment the dart was seen hanging from the corner of the boy's mouth.

The wound was closed with adhesive strips, and in two days' time the patient returned to Connecticut. He is perfectly well at this date, October 22d.

MORE CLINICAL FACTS REGARDING THE HYDROCHLORATE OF COCAINE.

By I. HERBERT CLAIBORNE, JR., M. D.,

CLINICAL ASSISTANT TO THE CHAIR OF OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC.

IN the last issue of this journal were reported several cases illustrative of the remarkable anæsthetic effect of the hydrochlorate of cocaine, occurring in the private and hospital practice of Dr. E. Gruening of this city.

Since the last publication Dr. Gruening has performed two iridectomies (for artificial ripening of cataract), one operation for squint, and one for pterygium, and has applied the actual cautery to the mucous membrane covering the inferior turbinated bone, without causing pain.

In addition to these, there is also recorded below an advancement of the external rectus, in which there was considerable pain:

CASE I.—A German, a male, aged seventy-five, with unripe senile cataract. Twelve drops of a two-per-cent. solution of cocaine hydrochlorate were instilled into the eye—four drops every five minutes. Five minutes after the last instillation all the steps of artificial ripening of cataract, even the clipping of the iris, which had given pain in all the other cases, were tolerated without pain or resistance. In fact, the patient was giving the history of his trouble during the operation, and asked for the chloroform after it was finished.

CASE II.—An Irish woman, aged fifty, also with unripe senile cataract. Instillations were made as in Case I, and artificial ripening was done without pain in any step of the operation.

CASE III.—C. D., a female, aged twenty-seven, with strabismus convergens of the left eye. Twelve drops of the solution, instilled as in Case I, rendered the eye completely anæsthetic. As the internal rectus was pulled forward and cut, the patient winced slightly. When asked, after the operation, if she had had pain, she said she had had none, but had felt us pull something.

CASE IV.—Same patient as in Case III. Advancement of the external rectus of the same eye. Instillations as before. The patient tolerated the speculum, the forceps, and the cutting of the conjunctiva without pain. All the other steps of the operation, however—exposure of muscle, tenotomy, and insertion and tying of sutures—were attended with considerable pain. Tenotomy of the internal rectus of same eye had been done five days before.

CASE V.—A young man, aged nineteen, with pterygium internum, encroaching about two lines upon the cornea. Instillations were made as in the preceding cases. There was absolutely no pain or resistance during the operation. As the first suture was finished, the patient said he felt very weak and asked for water. Immediately afterward he vomited profusely. When asked if the pain had caused him to vomit, he said no, that it was from fright. A few minutes after the operation he complained of the stitches hurting him a little.

CASE IV.—S. M. H., a male, aged forty, with hypertrophy of the mucous membrane covering the inferior turbinated bone. The patient was placed in the operating chair, with his head somewhat lower than his body, and eighteen drops of the same solution were instilled into the inferior meatus, and, as nearly as possible, on the mucous membrane of the inferior turbinated bone. Six drops were instilled every three minutes. A few minutes after the last instillation the actual cautery was applied. The patient said he had had no pain at all, and seemed very much surprised and pleased.

In his private practice, Dr. Gruening has several times passed the canaliculus knife and probes in cases of lachrymal stricture, with great amelioration though not complete absence of pain.

To sum up our clinical experience, so far, with the agent, we have, then, two cataracts, three iridectomies, one squint, one advancement, and one pterygium—not including foreign bodies in the cornea.

In the two cataracts and in one iridectomy there was slight pain in cutting the iris; in the two other iridectomies there was no pain. There was no pain in the squint, considerable pain after we had got beneath the conjunctiva in the advancement, and no pain, but vomiting, probably from fright, in the pterygium.

Considering the high price of the hydrochlorate of cocaine, it has been suggested to the minds of many that its cheaper sister alkaloids—caffeine, theine, theobromine, and guaranine—might be possessed of similar anæsthetic properties.

As there are no stable single salts of these alkaloids, extensive experimentation has been made by Dr. Gruening with the double salts, the salicylate of sodium (two and a half per cent.) and caffeine (four per cent.), and the benzoate of sodium and caffeine (four per cent. each) in watery solution.

In no case, however, has he obtained any anæsthetic effect with either.

Listerism in Abdominal Surgery.—Mr. Tait and Mr. Thornton are again at variance on the old subject of statistics, judging by a letter from the latter gentleman, published in the "American Journal of Obstetrics" for September, in which Mr. Tait is called to a sharp account for his strictures upon antiseptic ovariotomy. Mr. Thornton states that his own results are from three to eleven per cent. better than Dr. Bantock's, while Dr. Bantock's "Listerian" mortality is eight per cent. lower than that of his non-antiseptic cases."

THE
NEW YORK MEDICAL JOURNAL.

A Weekly Review of Medicine

Published by
D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, NOVEMBER 1, 1884.

A REMONSTRANCE AGAINST THE ACCEPTED THEORY OF
INFLAMMATION.

HE must be either a very rash or a very bold man who can deliberately set himself up as the extinguisher of doctrines which have been taught to generations of medical men all over the world. Yet its very audacity, apart from the high reputation of the writer, demands attention for Mr. T. Wharton Jones's "remonstrance," published in a late number of the "Lancet." Medicine is still overgrown with venerable traditions, but we have already witnessed the uprooting of many an ancient theory, and, in this age of investigation, doubtless there will be many others to be cleared away by the same rough treatment. But to attack the doctrines of Cohnheim, to which so many of the present generation of medical men listened in their student days, to assure us that the white corpuscle, which has so often been followed in its erratic course, does not stray from the straight and narrow capillary way—this is radical indeed.

We wish that Mr. Jones had shown a little more of the "tender grace of courtesy," as Mr. Tait lately expressed it, in dealing with his opponents: and Cohnheim's great name, although it need not shield the lost teacher from criticism, should cause that criticism to be tempered with somewhat of reverence. But as to the "remonstrance." "It is addressed," says the writer, "to professors of physiology and pathology, against teaching, in their writings, lectures, or occasional orations, that the white corpuscles of the blood escape from the interior of small vessels, until they have verified it scientifically, by actual observations of their own, as a fact in nature." With this open challenge, the author proceeds, in vigorous English, to state his own observations upon the subject, which, he says, antedated those of Cohnheim and his followers by several years.

His deductions are: 1. That the white corpuscles do not emigrate from the interior of blood-vessels by forcing their way through the vessels' walls. 2. That, when these leucocytes are found in the extra-vascular tissues, the true explanation is, not that they have abandoned the vessels, but that the vessels have become destroyed and left their contents uninclosed. In other words, the free leucocytes are not to be regarded as the cause, but as the result, of an inflammatory process. The supposed white corpuscles which are so often described and figured as being caught in the act of making their way through a vessel's wall are not white corpuscles at all, but merely nuclei in the wall of the capillary.

In order to satisfy himself of the hopeless ignorance of the scientific world upon this subject—or, as he modestly expresses it, desirous of learning anything which might have escaped his notice on the point—Mr. Jones asked the opinions of "pro-

fessors of note," none of whom, he affirms, were able to satisfy him. Two gentlemen did invite him to their laboratories, and tried to make him see with their eyes the emigration of the leucocyte, but in vain; he still remained unconvinced.

Ordinarily, "seeing is believing," but whoever has ever seen, or supposed he was seeing, the emigration of white corpuscles in an inflamed mesentery, and been told by a teacher of renown in pathology that such was the case, and has all these years treasured the conviction that both he and his teacher were right, must now suppose that his senses deceived him, and that his teacher of pathology was the victim of a like deception. To this distressing conclusion does the learned writer point him, and with no way of escape offered. The only inference to be drawn from his statements is, that the majority of experimental pathologists are vitally wrong in regard to one of the elementary observations—one that is supposed to be within the range of the veriest beginner. Nor is there any hope for them, or for their coming pupils, unless they make a radical change in their ideas and acknowledge that what they have always regarded as emigrating white corpuscles are not white corpuscles at all, but stationary nuclei. This is a surrender that we do not look for at present.

The practical impression left after a perusal of Mr. Jones's polemic is that, for a reformer, he is altogether too sudden and violent in his methods. We do not object to his boldness in attempting to overturn a doctrine which has received such universal support; on the contrary, we admire his originality, and give him due credit for his researches. The simple suggestion is offered, however, that the author of a new theory would do well to fortify it by a series of patiently acquired facts before he proceeds to tear down a structure which has itself not been reared in a day. The destroyer of an old faith should certainly be prepared to offer some better substitute.

OPENING WEEK AT THE LONDON MEDICAL SCHOOLS.

IN accordance with time-honored custom, the 1st of October witnessed the great speech-making which inaugurates the opening of the hospital-schools of the British metropolis. It is a peculiarity of our English brethren that no institution, whether a flower-show or a medical school, is considered as fairly "opened" unless the ceremony has been duly preceded by an address—preferably by some exalted personage, or, failing that, by one who, if less elevated, is perhaps more intelligent. Seriously, all this speech-making produces not a little that is interesting and readable. Especially is this the case when one of the distinguished members of the medical profession makes the address. The annual addresses delivered before the students by men who stand in the front rank of medicine furnish us with a very good idea of the general drift of English thought on medical subjects. This year the British journals complain that too many of the lecturers shot over the heads of their youthful hearers, and one critic even goes so far as to characterize the October oration as a bore, suggesting as a substitute for the scattered inaugurals a monster mass-meeting of all the schools, at which the enthusiasm of those present should be raised to a

high pitch by "the burning words of a Gladstone, a Lidden, a Huxley, or a Paget."

It is rather severe on the gentlemen who give so much time and thought to the preparation of addresses to have the expression "stereotyped" applied to them. For us, they certainly possess no common interest, since they not only contain the noble thoughts of noble men, but point out the ideal at which the English student is expected to aim. Dr. Gowers's remarks in particular, are very suggestive, combining as they do sound wisdom with the broadest humanity. If these addresses indicate, as we think they do, the spirit of British medical training, we may well regard its standard as high and its aims as pure and true. We wish that more of our own schools were opened with some of the same "plattitudes."

MINOR PARAGRAPHS.

CHEESE POISONING IN MICHIGAN.

At the recent quarterly meeting of the Michigan State Board of Health, the Secretary, Dr. Henry B. Baker, to whose courtesy we are indebted for an account of the proceedings, continued his report on this subject. Seven outbreaks within the State had been reported during the year, one hundred and ninety persons having been affected in all, but none fatally. The symptoms were very similar in all the cases, consisting of pain in the stomach, muscular cramps, coldness of the extremities, and great prostration, with violent retching and purging, lasting for several hours. In most cases, the larger the amount of cheese that had been eaten the more violent were the symptoms. Specimens of the Lowell cheese had an acid reaction and a peculiar, strong odor, believed to be due to caprylic acid or caproic acid. Examined with a one-tenth-inch immersion objective, this cheese was found to contain the mycelium of a mold, and to be swarming with several kinds of bacteria in active movement. Specimens had been sent to Professor Vaughan, of the University of Michigan, and to Professor Burrill, of the Illinois State Industrial University, for further examination and experiment.

THE RELATIONS BETWEEN MEDICINE, SURGERY, AND OBSTETRICS IN LONDON.

A LETTER from Dr. Robert Barnes, in the "American Journal of Obstetrics" for September, has attracted much attention, not because of any new facts therein stated, but by reason of the clear and forcible way in which the case is put. It has long been known to us in America that our English brethren drew a very sharp line between "physicians" and "surgeons." But we believe that the writer's statements as to the position occupied by the English obstetric physician have proved a revelation to most of his American readers. We are so accustomed to look upon London medical men as the willing subjects of tradition and precedent that Dr. Barnes's letter arouses not merely our surprise, but our admiration at his boldness in casting off the chains which have so long bound his branch of the profession. The absurd jealousy of English surgeons toward their medical colleagues and the narrow field to which the latter are limited are nothing compared with the limitations imposed upon the obstetric physician.

We can imagine the commotion which this letter will cause in the London surgical ranks. Doubtless there will be a reply from the other side, but Dr. Barnes may rest assured that our sympathies are with him in his struggle against the "arbitrary conventional rules which have become obsolete by the progress

of medicine, and the juster and broader system of medical education now prevailing."

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 28, 1884:

DISEASES.	Week ending Oct. 21.		Week ending Oct. 28.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	50	13	60	11
Scarlet Fever.....	25	5	31	4
Cerebro-spinal meningitis.....	6	4	4	4
Measles.....	36	4	41	3
Diphtheria.....	43	30	45	28

Bellevue Hospital Medical College.—At a meeting of the faculty, held October 23d, Dr. Paul Grawitz, assistant to Professor Virchow, of Berlin, was appointed professor of pathological anatomy and director of the Carnegie Laboratories. We learn that no doubt is felt that Dr. Grawitz will accept the appointment.

The Fairfield County, Conn., Medical Society will hold its semi-annual meeting at Bridgeport, in the new Bridgeport Hospital, on Tuesday, November 11th, beginning at 10 A. M. A paper will be read by the Vice-President; an address on "Some of the Famous Surgeons and Hospitals of Europe" will be given by Dr. Robert F. Weir, of New York; and a case will be related by Dr. A. E. Adams, of Danbury. A dinner is to be given at 1 P. M., and the dedication exercises of the new hospital will begin at 2.30 P. M. It is expected that the Governor of the State, with his staff, the Mayor of Bridgeport, and a number of other distinguished persons will be present. The hospital will be open for inspection after 9 A. M.

The University of Vermont.—We learn that Dr. W. Oliver Moore, one of the surgeons of the Manhattan Eye and Ear Hospital, of New York, has been appointed professor of diseases of the eye and ear in the medical department of the university; also that Dr. Stephen S. Burt, of New York, has been appointed to the chair of physical diagnosis.

The Death of Dr. Allen S. Church, a well-known and highly respected practitioner of this city, took place on Friday, October 24th. Dr. Church was a graduate of the Castleton Medical College, of the class of 1848, and a member of the Medical Society of the County of New York, of the New York County Medical Association, of the Academy of Medicine, and of several other medical societies. He was a native of Massachusetts.

The Death of Dr. William H. Ensign occurred on Sunday, October 26th, in the fiftieth year of his age. Dr. Ensign was a native of Connecticut and a graduate of the Medical Department of the University of the City of New York, of the class of 1861. During the late civil war he served with credit as an assistant surgeon in the army, and at the time of his death he was one of the police surgeons of this city.

The Death of Dr. Oulmont, of Paris, is announced in our French exchanges. He had reached the age of seventy years, and was an honorary physician to the Hôtel Dieu. The "Progrès médical" states that he left the sum of eighty thousand francs in bequests to various scientific and charitable organizations.

Professor Semmola, of Naples, as we learn from the "Progrès médical," has recovered from an attack of the cholera.

The Death of Professor Somma, of Naples.—While the whole medical world will rejoice at Professor Semmola's recovery, it will be equally pained to learn of the death of Professor Luigi Somma, who fell a victim to the same disease on the 19th of September. Dr. Somma was the editor of the "Archivio di Patologia Infantile," a most creditable journal of pædiatrics.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 19, 1884, to October 25, 1884:*

AIDEN, CHARLES H., Major and Surgeon. Relieved from duty at Fort Yates, D. T., and ordered for duty at Fort Snelling, Minn. S. O. 125, Department of Dakota, October 20, 1884.

VICKERY, R. S., Major and Surgeon. During temporary absence of Major J. C. McKee, Surgeon, U. S. A., Medical Director of the department, in addition to his other duties, will assume charge of the office of the Medical Director. G. O. 34, Headquarters Department of the Columbia, October 8, 1884.

WINNE, C. K., Captain and Assistant Surgeon. In addition to his duties as Post Surgeon at Benicia Barracks, will also attend the sick at Benicia Arsenal, Cal. S. O. 122, Headquarters Department of California, October 13, 1884.

STRONG, NORTON, First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Union, N. M. S. O. 198, Department of Missouri, October 4, 1884.

PHILLIPS, JOHN L., First Lieutenant and Assistant Surgeon. Transferred from Department of the East to Department of Dakota. S. O. 245, A. G. O., October 18, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending October 25, 1884:*

BLOODGOOD, DELAVAN. Promoted to the grade of Medical Director, August 22, 1884.

OBERLY, AARON S. Promoted to the grade of Medical Inspector, March 28, 1884.

WELLS, HENRY M. Promoted to the grade of Medical Inspector, August 22, 1884.

Society Meetings for the Coming Week:

MONDAY, November 3d: Medico-Chirurgical Society of German Physicians (private); Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; Providence, R. I., Medical Association; St. Albans, Vt., Medical Association.

TUESDAY, November 4th: New York Neurological Society; Buffalo Medical and Surgical Association; Elmira, N. Y., Academy of Medicine; Ogdensburg, N. Y., Medical Association; Medical Society of the County of Hudson, N. J.; Androscoggin County, Me., Medical Association.

WEDNESDAY, November 5th: Medical Society of the County of Richmond, N. Y.

THURSDAY, November 6th: New York Academy of Medicine ("On the Pathological Anatomy of Sensory Aphasia," by Dr. R. W. Amidon; "The Asiatic Cholera at Suspension Bridge in 1854, and its Lessons—what we know of Cholera," by Dr. Frank H. Hamilton); Medical Society of the County of Orleans, N. Y.; Society of Physicians of the Village of Canandaigua, N. Y.; Boston Medico-Psychological Association.

FRIDAY, November 7th: Practitioners' Society (private).

SATURDAY, November 8th: New York Medical and Surgical Society (private); Obstetrical Society of Boston (private); Worcester, Mass., North District Medical Society.

Letters to the Editor.

THE EFFECTS OF ALCOHOL POISONING ON THE HEART.

OSWEGO, N. Y., October 24, 1884.

To the Editor of the New York Medical Journal:

SIR: I have been forcibly impressed with the effects of alcoholic poison upon the action of the heart in several cases that have come under my observation—cases that gave no evidence of mental disturbance characteristic of *mania a potu*. The mind was clear and rational, save an expression of an overpowering sense of fear of speedy dissolution. The exhibition of anxiety, fear, and sometimes terror, which no assurance from me could allay, was pitiable. This state of mind is instinctive, due to the effect of alcoholic poison upon the action of the heart. It is analogous to the overpowering sense of fear of impending dissolution experienced in angina pectoris, and in the sudden paroxysms induced by fatty degeneration of the heart, but there is no dyspnoea or orthopnoea. The subjects had been drinking daily, for a long time, a large quantity of alcoholic stimulants, until the system had become thoroughly saturated and poisoned. The stomach was irritable and refused to retain food; the pulse small, thready, and intermittent; the heart's action very irregular; the sleep fitful and disturbed, the patients waking with a start, in a nervous tremor and abject terror, begging for more drink and insisting that they must have it or they would die.

This thirst and craving for more drink are, in a great measure, due to the demand of the flagging heart for support to enable it to continue its work; the demand is imperative, hence the instinctive sense of fear, amounting to, in some cases, abject terror. A heart-stimulant and restorative soon appeases the desire for more stimulus and allays the fear. I found that nitro-glycerin, one one-hundredth of a grain, given every half-hour or hour, soon steadied the pulse and gave strength and uniformity to the heart's action, and caused the importunate demand for more alcoholic stimulus and the abject fear to cease. The effect was almost immediate; the pulse soon became full and steady, and the heart restored to its rhythmic action; the face soon became flushed, and they complained of a sense of cerebral fullness, which soon passed off.

October 22d, about 1 P. M., I was hastily called to visit Mr. D., a resident of the western part of the State, who was here on business, and had, he told me, been drinking during the past three weeks, on the average, fifteen glasses of lager beer a day, winding up each night on a half-pint of whisky to procure sleep. He had vomited twice that morning, felt very weak and nervous, and said that he feared he would not live long. His pulse was small, feeble, and intermittent; the heart's action was very irregular. I gave him one third of a grain of sulphate of morphia, and prescribed thirty grains of bromide of potassium, to be taken every fourth hour, well diluted with water, until sleep was induced, and ordered a bowl of beef-tea to be taken at intervals as his stomach could retain it. I also ordered entire abstinence from alcoholic stimulus, and trusted to a friend who was with him to see that the order was obeyed.

I called again about 6 P. M., and found him exceedingly nervous and depressed, more alarmed as to his recovery, and insisting that his wife should be sent for. His pulse was a little more steady. He had taken advantage of a brief absence of his friend, and slipped down below and taken two drinks of whisky at the bar, and had vomited some oyster-broth which he had taken in place of the beef-tea. I ordered a continuance of the bromide of potassium, and left one fourth of a grain of sulphate of morphia, to be taken in the night if sleep was not obtained.

He had had about two and a half hours of fitful, disturbed sleep in the afternoon.

I called the next morning at eight, and found him in a deplorable condition; he was in a violent nervous tremor, the pulse feeble and intermittent; he was sure that he would not live much longer, and insisted that his wife should be sent for immediately. His friend told me that he had had two intervals of sleep of about two hours and a half each, waking up each time in a nervous, frightened state and begging for more stimulus, which he had refused to give him; he had vomited the morphine and bromide of potassium. I immediately gave him an ounce of whisky and a pill of nitro-glycerin. I remained by him about an hour; his pulse immediately began to gain strength, fullness, and steadiness, which continued about half an hour, and it then began to grow weak and unsteady. I then gave him another pill, which soon restored the strength and evenness of the pulse, and he ceased his abject entreaties for more whisky, which up to that time had been almost constant, and expressed no more fear of dying. His stomach remained irritable through the day; he was only able to retain small quantities of iced milk; the pills were repeated every second hour until the afternoon, when they were discontinued, as his pulse had recovered from its weakness and irregularity. He was able to return to his home the next day.

An acquaintance, of unusual strength and vigor of constitution, has studied the effects of alcoholism upon his own person; it invariably causes an irregular and intermittent pulse and irregular action of the heart, but seldom affects his brain.

A. S. COE, M. D.

Proceedings of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK

Annual Meeting, held October 27, 1884.

The President, Dr. S. O. VAN DER POEL, in the chair.

The Eligibility of Homœopathic Graduates to Membership.—The minutes of a meeting of the Comitia Minora were read, showing that among the candidates for membership there were two gentlemen who were graduates of homœopathic colleges. To these candidates the following-named questions had been put: 1. Whether they belonged to a homœopathic medical society. They had answered, "No." 2. Whether they were willing to drop their sectarian name. They answered that they had never practiced under a sectarian name, and never expected to do so. 3. Whether they were connected in any way with any homœopathic medical journal. To this they had answered, "No." 4. Whether they were willing to be governed by the laws of the Medical Society of the County of New York. They had answered, "Yes." The Comitia therefore recommended them for membership.

Dr. A. JACOBÍ said that Dr. ELLSWORTH ELIOT, who was unable to be present, had requested him to offer a resolution to the effect that a diploma from a homœopathic medical college did not entitle the holder to membership in the society.

The resolution was laid on the table.

The two candidates were then unanimously elected to membership.

The Treasurer's Report was read and approved, and an assessment of two dollars was ordered to be levied in addition to the annual dues for the coming year, this sum being considered necessary for the prosecution of certain work undertaken by the society.

Election of Officers.—There being but one name on the list for each of the following offices (the other nominees having withdrawn their names), the secretary was instructed to cast an affirmative ballot for each of them. This having been done, Dr. DANIEL LEWIS was declared elected president; Dr. LAURENCE JOHNSON, vice-president; Dr. WESLEY M. CARPENTER, secretary; Dr. CHARLES H. AVERY, assistant secretary; and Dr. ORLANDO B. DOUGLAS, treasurer.

On ballot, five censors were elected, as follows: Dr. JOSEPH W. HOWE, Dr. FRANCIS M. WELD, Dr. HENRY T. PEIRCE, Dr. FREDERICK R. S. DRAKE, and Dr. WILLIAM OLIVER MOORE.

The Report of the Board of Censors, including the report of the council for the society, was read by Dr. J. W. HOWE. These documents dealt chiefly with the results of the work undertaken by the society in contesting the validity of the charters of certain medical colleges.

The Report of the Committee on Hygiene was read by Dr. VAN SANTVOORT, and touched upon the subject of the public-school fund, the public baths, the ventilation of sewers, and contagious ophthalmia in residential schools. Regarding the ventilation of sewers, the report stated that, while the system now in use might be open to criticism, the present committee was not prepared to recommend any better plan. That part of the report relating to contagious ophthalmia among the inmates of industrial and residential institutions for the young in and about New York city dealt with the statistics of eye diseases of a communicable nature among this class, the means of their introduction and spread, and the injury occasioned thereby, and recommended the passage of a law making it compulsory, before receiving a child into one of these institutions, to submit its eyes to examination by a competent physician; and, second, that the eyes of all inmates be examined from time to time, and that those found to be suffering from contagious ophthalmia be properly isolated and treated.

Dr. C. R. AGNEW said that about two years ago, by request, he examined into the extent to which contagious ophthalmia prevailed in residential institutions in and about New York, and he had become convinced that the eyes of many of the inmates had been lost or permanently injured by this disease, probably introduced by a new-comer brought directly from a filthy home by some society whose object was to prevent cruelty to children. Some legislation upon the subject was desirable, and he therefore moved that the present Committee on Hygiene be continued as a special committee on contagious ophthalmia, to report at an early date. Carried.

Prize Essays.—Dr. C. C. LEE, of the Committee on Prize Essays, reported that but a single essay had been submitted, and that this, while it showed a good deal of learning and research in an effort to establish the mutual histological interdependence of cancer and tubercle, was not considered by the committee as worthy of the prize.

The Society declines to indorse a Candidate for Public Office.—Dr. RUDOLPH TAUSZKY moved that the society indorse the nomination of Dr. M. J. B. Messener for the office of coroner.

Dr. JACOBÍ opposed action in the matter for two reasons: First, that the county and the State medical societies had expressed their disapproval of the office of coroner as it now exists; and second, that this was not a proper place to bring in politics.

The motion was laid on the table.

The Qualification for Membership.—Dr. JACOBÍ moved a suspension of the by-laws, so as to allow of action upon a resolution of the following purport:

Resolved, That the Comitia Minora recommend no applicant for membership unless he is a graduate of a medical college in

good standing, or a licentiate of a non-sectarian State or county medical society of this or some other State; or, if his certificate is of a sectarian character, unless the applicant declares in writing that he is non-sectarian in principle and practice.

This resolution could be acted upon at the present meeting only by a suspension of the by-laws, which would require unanimous consent of the members present.

Dr. C. R. AGNEW was opposed to the suspension of the by-laws, for the resolution seemed to be one requiring deliberation, and there was no necessity of its immediate adoption.

Dr. H. G. PIFFARD explained that the resolution could be acted upon only at an annual meeting, and, if the by-laws were not suspended on the present occasion, would have to lie over until next year.

Dr. AGNEW still doubted the wisdom of hasty action in the matter, and the resolution was consequently laid over.

Amendments to the By-laws.—An amendment to the by-laws was passed, abolishing the meeting in June. Another proposed amendment, providing for forfeiture of membership for non-payment of dues, was laid on the table, but it was ordered that the Comitia Minora report at the next meeting some efficient plan of inducing delinquent members to pay their dues.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of October 8, 1884.

The President, Dr. GEORGE F. SHRADY, in the chair.

Carcinoma of the Stomach.—Dr. SATTERTHWAITE was called in consultation, on the 7th of September last, to see a gentleman who had had a light hemiplegic attack, affecting the right upper and lower extremities. He largely recovered the use of the extremities within twenty-four hours. On inquiry, it was learned that the patient had been losing flesh rapidly during the preceding month, less rapidly for six months, and to some degree during two years. So far as could be learned by his physician, he had not been suffering from any special disease. There was nothing abnormal about the urine, lungs, or heart; there had been some pain in the epigastric region, but no tumor could be felt. For a month he had been unable to retain solid food, and a cachectic appearance developed. Two weeks before death the patient had another hemiplegic attack, was unable to move the right lower and upper extremities, and had difficulty with speech and swallowing, but after a short time this difficulty almost entirely disappeared. The last four or five days of his life he refused to take food, saying he preferred starvation to the pain attending vomiting. Death took place from starvation. At the post-mortem examination a circular patch of thickening, of about the size of a fifty-cent piece, was found at one side of the pyloric end of the stomach. The patch could be felt but not seen. Doubtless it had acted somewhat as a valve, obstructing the exit of food through the pyloric opening, which was constricted to the size of a lead-pencil. The pancreas contained a few hard nodules. Dr. Satterthwaite had preferred to exhibit the specimens to the society in their fresh state, before a microscopical examination had been made, but there was little doubt that the disease was carcinoma.

The President remarked that it would seem that malignant disease would have made greater progress within two years.

Dr. SATTERTHWAITE had seen a case in which the cancerous tumor had been felt at the pylorus for two years before death finally took place, and the symptoms of cancer dated back of that period.

Dr. J. C. PETERS said that the first specimen presented to the society, in 1844, was similar in appearance to that presented by Dr. Satterthwaite, and the patient had had many like symp-

toms, but the thickened patch at the pyloric end of the stomach was found on examination not to be carcinoma, but hypertrophied areolar tissue. It was considered a rare condition.

Dr. VAN GIESON thought the duration of gastric symptoms could not always be relied upon as an indication of the duration of the cancerous disease, as the latter might be engrafted upon the former.

Dr. CARPENTER mentioned a case in which he had found a cancerous nodule, about an inch in diameter, situated about three inches from the pylorus, but the patient had not complained of gastric troubles during life.

Naso-pharyngeal Fibro-Sarcoma.—Dr. LINCOLN showed a specimen which he had removed, July 22d, from a boy, sixteen years of age, who had never been very strong, and who had always suffered from nasal catarrh. He first noticed obstruction to nasal respiration, together with a tumor, in 1881. From this date he had suffered from frequent severe nasal hæmorrhage, usually coming on after active exercise, but sometimes during sleep. A physician had attempted to remove the tumor, which could then be seen through the nostril and mouth, by the ordinary polypus-forceps, but had failed. Dr. Lincoln saw the patient first, through the courtesy of Dr. Satterthwaite, on July 12th, at which time there was a noticeable fullness on the right side of the nose. The right nostril was filled to the margin by the growth, which pressed the septum to the left; the soft palate was deflected from the perpendicular, and below it, filling the naso-pharyngeal space, the tumor could be seen, apparently having its principal attachments to the vault of the pharynx and the roof of the nostril. It was exceedingly vascular, and evidently growing rapidly; therefore an immediate operation was advised, without preliminary treatment by electrolysis. On July 22d the galvanic-cautery wire was applied to the base of the tumor while the patient was under the influence of an anæsthetic, and Dr. Lincoln succeeded in cutting through the pedicle and drawing the tumor out entire through the mouth, no hæmorrhage taking place during the operation. The tumor measured four inches in its greatest length, and two inches and a half in thickness. The surface of attachment, which measured two inches by one and three quarters, was then cauterized. The weight of the growth was two ounces and three quarters. A week after the operation the cut surface presented a healthy appearance. The patient would not give his consent to a reapplication of the cautery for the purpose of preventing a renewed development of the growth.

The President thought there could be no comparison between this mode of operating and the old mode of preliminary tracheotomy, tamponing the pharynx, and removing the upper jaw. It seemed, however, that there were some cases of naso-pharyngeal tumors in which the wire could not be applied to the base of the tumor, on account of its extensive attachments. He mentioned two cases in which he had operated by removal of the upper jaw, the tumors having extensive attachments to the base of the skull, etc. One of the patients died, apparently as the result of an extension of the growth into the skull, and in the second case the result was similar, although death took place later. He now had a patient who was begging for a similar operation, but he hoped first to have a consultation with Dr. Lincoln as to the advisability of trying the galvanic cautery. The great difficulty in this class of cases was that usually they did not come under observation until it was impossible to apply the wire, and the general health was too greatly reduced from repeated hæmorrhages, etc., to make success from a surgical operation at all probable.

Dr. HOWE thought that even in the bad cases referred to, with such extensive attachments, the tumor might be removed piecemeal by the wire.

The President had had one such case in which a gentleman skilled in this manner of operating had removed a portion of the tumor with the wire, but, while the patient's condition was much improved thereby, the pain consequent on ulceration at the points where the wire had been applied deterred him from submitting to further treatment.

Dr. SATTERTHWAITE thought the operation which Dr. Lincoln had performed, at which he was present, had required a great deal of manual dexterity. A distinguished throat specialist had said that the tumor could not be removed except by first removing the upper jaw, but Dr. Lincoln performed the operation with the galvanic-cautery wire with a single application of the loop. The patient had had no hemorrhages since the operation, and had gained greatly in flesh and strength. He had been impressed very favorably with the operation, and would be glad to hear Dr. Lincoln's further experience with it.

Dr. LINCOLN said he had had six cases, two of which were still under treatment. In the four other cases he believed there was no possibility of recurrence. He had had no fatal result. With regard to the difficulties overcome during the operation, he referred to a case in which he had operated in 1875. The patient had been operated upon by the late Dr. Willard Parker, and also by Dr. Lutkins, who referred him to Dr. Lincoln. At the time when he saw him, the boy, five feet and a half high, weighed only sixty-eight pounds. His condition was such that death seemed inevitable, and several surgeons had said that no treatment was justifiable. The tumor had so developed as to cause protrusion of the right eye, and projected through the nostril to the margin of the upper lip, and into the mouth to such an extent that the tongue had to be depressed at night with a spatula to enable the patient to sleep. There had been frequent hemorrhages. Dr. Lincoln began preliminary treatment by electrolysis, making about twenty-five applications. The growth of the tumor was thus checked, hemorrhage ceased, and the patient recuperated so that the final operation could be undertaken with perfect safety. The wire was applied, and the tumor was removed entire without any hemorrhage. Some applications of the cautery were made subsequently, and there had been no signs of return of the growth since. The other cases were similar, but not quite so pronounced.

Fibro-Cyst of the Uterus.—Dr. PRUDEN presented a specimen which had been sent him by Dr. C. C. Stockard, of Columbus, Miss., the history of which had been published in the "Medical Record" for August 16, 1884. It was interesting principally on account of its large size. Together with the fluid contents which had been drawn off six days before death, it weighed one hundred and thirty-five pounds. Eight gallons and seven pints of fluid had been withdrawn by tapping. The microscopical examination showed the specimen to be a cystic fibroma of the uterus. It had developed in a negress who had borne children.

Intestinal Obstruction.—Dr. C. W. KNIGHT presented a part of the intestine and uterus which had been removed from the body of a negress, thirty-five years of age, unmarried, who had been the subject of constipation for a good many years, with frequent attacks of colic, but had never consulted a physician. Frequently her bowels did not move once in two weeks. After her last attack had continued two weeks she began to take purgative medicines, and in the third week she sent for a physician, who found no constitutional disturbance. She was up and about her room until the last day of her life, when she began to vomit copiously, had enormous distension of the abdomen, and died suddenly. At the autopsy the small intestine was found to be distended and congested, and about five inches from the cecum there was a constriction between two fibrous bands, which had produced a furrowed appearance in the gut, but had not caused

ulceration. The obstruction was immediately relieved on cutting the constricting bands.

Meeting of October 22, 1884.

The President, Dr. GEORGE F. SHRADY, in the chair.

General Carcinosis.—Dr. JOHN A. WYETH presented specimens obtained from a case in which carcinoma probably originated in the lumbar glands, with metastasis to the anterior mediastinum, liver, and bladder. The patient, a German, thirty-eight years of age, a machinist, was admitted to Mt. Sinai Hospital, September 10, 1884. Last May he noticed a swelling upon the left side of the umbilicus, which increased in size, extending down nearly to the symphysis pubis and into the left lumbar region, and gave him much inconvenience by its size and position. The patient lost eighty pounds in weight within four months, coughed, and sometimes expectorated blood. There was some bulging on the left side of the thorax, and enlargement of the supra-clavicular and axillary glands. The thoracic and abdominal tumors were nodular to the feel, and painful on pressure. Over the left side of the chest there was diminished respiratory murmur, with crepitant and subcrepitant râles and some dullness. There was marked laryngitis, with loss of voice and spasmodic cough. September 16th the patient suffered from severe pain in the left leg and thigh, the limb became cold and mottled, and the foot was anæsthetic. There was no pulsation in the femoral artery. The swelling of the left lower extremity continued to increase, with pain along the course of the artery. The patient's condition grew worse, and he died on the 15th of October. The visiting staff of the hospital agreed that there had been partial occlusion of the external iliac artery, which had given rise to coldness in the left lower extremity. Afterward swelling and hemorrhagic blebs occurred from thrombosis secondary to the partial occlusion. At the autopsy the tumor was found to occupy the left inguinal and lumbar regions, being covered by adherent mesentery and firmly attached to the vertebral column, the descending colon, and the left kidney. It arose apparently from the glands of the dorsal and lumbar regions, and completely surrounded the aorta and vena cava. The left external iliac artery was flattened, and there was thrombosis of the iliac vein extending into the left femoral. The left anterior mediastinum and lung were the seat of carcinomatous new growth, the tumor pressing upon the trachea and the great vessels; there were cavities in the left lung, and marked bronchitis and laryngitis. There were foci of carcinomatous degeneration in the liver and bladder.

The chief point of interest in the history of the case was the fact that last spring Dr. Gerster removed the left testicle, which he presented to the society as an illustration of tubercular testis. The records of the German Hospital also showed that the affection of the testicle had been regarded as tubercular.

Foreign Body in the Bronchus.—Dr. WYETH related a case, and showed the specimen. [See page 487.]

With regard to Dr. Wyeth's second case the President thought it possible that, had the patient been less profoundly under the influence of the anæsthetic, the foreign body might have been coughed up at the first exploration. He believed that most foreign bodies which entered the air-passages were, sooner or later, dislodged by violent expiration. In a case in which the body was pointed, the point being upward, as in Dr. Wyeth's case, he thought it safer to perform tracheotomy and explore the trachea and bronchi. Round bodies might perhaps better be treated on the expectant plan. He was once enabled to remove the coiled spring of a clothes-pin from the upper part of the larynx of a boy who was apparently suffocating, using his fingers to grasp the foreign body.

Dr. J. LEWIS SMITH mentioned the case of a child which swallowed part of a nut-shell, developed fibroid pneumonia, afterward coughed up the offending piece, and recovered completely.

Dr. W. M. CARPENTER remarked that it was an old method, in cases in which a foreign body had entered the air-passages, to take the patient by the ears and violently draw the head forward and upward, at the same time striking him on the back. He was under the impression that, at a previous meeting of the society, at which this subject was up for discussion, it was shown that, as a rule, it was safer to treat such cases on the expectant plan, as in most instances the foreign body would be expelled by a violent expiratory effort.

Tumor of the Breast.—Dr. W. P. NORTHRUP presented a specimen of tumor of the breast which had been removed by Dr. C. C. Lee from a woman forty-five years of age, the mother of ten children. A short time before the birth of the last child she noticed a small tumor of the breast, and when the tumor was removed, seven weeks after the birth of the child, it was of the size of an orange. It had given rise to some lancinating pain. The patient had been seen by five or six eminent surgeons of the city, all of whom pronounced the tumor malignant, and advised immediate extirpation. The tumor was very firm, and somewhat nodulated; the nipple was markedly retracted; there was no ulceration. As Dr. Lee cut down upon the tumor there gushed out a lot of foetid material, apparently pus, and all who were present thought he had cut into an abscess. The anterior aspect of the wall of the cavity was quite thin and ragged; the posterior was markedly indurated. The ragged walls were cut away, the wound was closed, and union took place almost throughout by first intention. There were a few enlarged axillary glands which were not removed, and which were now scarcely perceptible to the touch.

The specimen, which had been examined under the microscope by Dr. Northrup and Dr. Delafield, gave the impression that there had been an adenoma, and that afterward an abscess had formed within it. The case was rendered obscure by the fact that the adenomatous tissue was pervaded by inflammatory or granulation tissue. It contained numerous giant-cells. The prognosis was considered very doubtful.

The PRESIDENT had operated in a similar case about two years ago, the woman being forty years of age, and presenting a tumor answering in almost every respect to the description given by Dr. Northrup, except that there was no retraction of the nipple. The cyst-wall was so tense that when it was cut into the contents spurted a great distance. He also removed some axillary glands. He was then of the opinion that the prognosis was good, but he had since operated twice upon the same patient for enlarged glands in the neck, and she was now dying of suffocation from enlarged glands along the sterno-cleido-mastoid muscle, and from asthenia. He should regard the prognosis in Dr. Northrup's case as very serious. All the enlarged glands in the axilla should be removed in cases of amputation of the breast.

Dr. WYETH thought the giant-cells pointed to sarcoma or tubercle.

Ulcerative Endocarditis.—Dr. J. LEWIS SMITH presented a specimen from the case of a girl, aged five years, whose health immediately before the attack of which she died was good. Two years previously she had had double pneumonia, and two months before an attack of pertussis. She began to be sick the 16th of August last, with fever and loss of appetite. Pneumonia was suspected, but no definite signs developed. Dr. Smith saw the patient on the 25th of August, at which time the temperature in the groin was 104.5° F., the pulse 150, the tongue dry and furred, and the respiration moderately accelerated. The

urine and heart-sounds were normal. He was unable to make a clear diagnosis. On the 26th the patient had slept well during the night, had had two stools of normal appearance. Morning pulse 160, temperature in the groin 102.4°; in the evening she had an evacuation of dark blood. On the 27th the pulse was 160. She had had one normal evacuation from the bowels. On this day the patient began to vomit, and continued to vomit more or less every day until she died. The temperature varied on the same day from 105° to 101° F. There was also a daily variation in the pulse rate. On the 29th there was a passage of pure blood from the bowels. On the 4th of September the patient vomited blood. She died on the 5th, in a state of great prostration. There was no extravasation of blood under the skin until the last day of life. At the autopsy the mucous membrane of the stomach and intestine was found mottled by extravasation of blood. There were some points of extravasation of blood in the liver; none in the kidneys; also some in the lungs, and to a marked degree in the anterior and posterior lobes of the brain, part of the sulci being filled by extravasation of blood under the arachnoid. On the mitral valve there was a polypus three quarters of an inch long, which, according to microscopical examination by Dr. Northrup, contained numerous micrococci. The entire endocardium seemed to be much thickened. There were two other smaller polypi, covered with fibrin, attached to the heart-walls.

Leucocythemia.—Dr. COX mentioned two cases of abdominal tumor which had been diagnosed, the one to be an ovarian and the other a renal cyst, but examination of the blood had shown that the patients were suffering from leucocythemia, and they were thus spared an unnecessary abdominal section.

NEW YORK SURGICAL SOCIETY.

Meeting of October 14, 1884.

The President, Dr. ROBERT F. WEIR, in the chair.

Exsection of the Knee Joint.—Dr. L. A. STIMSON presented a patient upon whom he had performed exsection of the knee joint with an excellent result as regarded the form and function of the limb. The patient was a man, forty-five years of age, who entered Bellevue Hospital in April, 1884, complaining of the consequences of a suppurative arthritis with which he had been affected seven or eight years previously, the result of an unknown cause. Multiple incisions had been made on the front of the thigh just above the knee, through which pus had been evacuated. When the patient entered the hospital the joint was somewhat "springy," and whenever he made use of the limb for a day, or even for an hour or two, it would become so painful that he would be obliged to lie up for days and sometimes for weeks. The patella was immovable, the joint, as already stated, fixed but somewhat springy. The condition being looked upon as that of false or partial ankylosis, the operation of excision was proposed, and was performed on the 21st of April by making a straight incision across the front of the joint, as nearly as possible at the level of the articulation, with a liberating incision on each side, at the two ends of the transverse incision. After the soft parts were cut through, the knee was firmly flexed and the joint broken open, after which the pieces of bone were excised. That from the femur was about an inch in its greatest thickness, that from the tibia very thin. A second thin slice was removed from the femur to make the adjustment of the limb more accurate. The bones were then wired together on each side, and the incision was closed with a continuous catgut suture. Two short drainage-tubes were then inserted. Bichloride solution was used during the operation. The dressing consisted of iodoformed gauze, and was changed on the follow-

ing day, being saturated with blood. The limb was suspended in a posterior wire gutter in such a way that separation of the cut surfaces by sagging downward of the thigh and pelvis was avoided. The dressing was again changed on the 8th of May, a little more than two weeks after the first change was made, and the tubes were withdrawn. The wounds were found to be healed, except at the points of entrance of the drainage-tubes. The dressing was changed again on the 26th of May, the wires were removed, and the limb was put up in a plaster-of-Paris splint. It could now be observed that the direction of the limb was apparently perfect. There was no angular deviation, no rotation of the thigh outward and no turning of the foot inward, and the limp was not very marked.

In reply to a question, Dr. Stimson said there had been complete destruction of the articular cartilages, with roughening and partial union of the surfaces of bone.

THE PRESIDENT inquired whether any difficulty had been experienced in extracting the wires.

Dr. STIMSON replied that there had been none.

THE PRESIDENT said he had seen square nails employed for fixing the adjoining extremities of the femur and tibia in a number of instances, both in this country and abroad, and, so far as he had been able to observe, they worked admirably. The nails were extracted at the end of the third or fourth week, and without difficulty. He had seen a good deal of trouble attend the removal of wires. He asked Dr. Charles McBurney what methods he had employed for fixing the ends of the two bones together.

Dr. MCBURNEY replied that in the first cases in which he had operated he employed wires, but he had sometimes experienced a good deal of difficulty in extracting them, and in some cases had had to etherize the patient. In the last three cases in which he had operated he had tried to secure coaptation without the use of either wire or nails, and, though it was too early to report on the result in these cases, he believed that they would do well.

Dr. F. LANGE remarked that his experience with nails had been satisfactory.

Dr. STIMSON had reported one case to the society in which no wires had been employed, but the result was very unsatisfactory, the foot turning inward to a marked degree. The result was anticipated during recovery, because it was impossible to keep the patient straight in bed.

Dr. CHARLES T. POORE had frequently had difficulty in removing the wires, and in one case had left them in without any mishap.

Dr. ALFRED C. POST had once broken a wire off in attempting to remove it, in a case of ununited fracture of the radius, and the piece which remained in the bone had caused the patient but very little trouble.

An Inquiry into the Origin of the Use of the Ligature in the Treatment of Aneurysm.—Dr. STIMSON then read a paper with this title. [See page 477.]

Vascular Tumor of the Lip removed without Hæmorrhage by the Use of a Clamp.—Dr. POST presented a small specimen, which was of interest with reference to the manner in which it had been removed. It was a bleeding fungus, about 12 mm. in length, 9 mm. in breadth, and 7 mm. in thickness, which had grown from the posterior mucous surface of the upper lip near the median line. He had removed it without a medical assistant, hæmorrhage being prevented by the use of a large elliptical clamp upon the lip. The first suture was passed while the clamp was in position, but not tightened until after the clamp had been removed. But a few drops of blood were lost. The growth had not yet been examined with the microscope, but it was not believed to be malignant.

Recurring Carcinoma of the Arm; Capillary Drainage.

—Dr. THOMAS M. MARKOE presented an arm, the seat of secondary cancer. It had been removed from a lady past middle life, eighteen months after the removal of the breast, which had been done by a physician in Burlington, Vt. The tumor of the breast was probably carcinomatous. The patient remained well after amputation of the breast for about a year, and then began to complain of a great deal of pain in the left humerus. There was no special tumor of the humerus at any time, but there was increasing tenderness, and, after the lapse of a few weeks, the bone became flexible and could be bent at almost a right angle. The patient came to the city, and Dr. Markoe removed the arm at the shoulder joint by the ordinary operation, making a long deltoid and rather a short axillary flap. The healing of the wound was rapid and extremely satisfactory. The bone was found to be entirely flexible, due to a series of breaks at various points. Just below the neck there was a distinct fracture, which had been appreciated before the operation.

Dr. FERGUSON had made the following report upon the specimen: "The soft parts being partially removed, the left humerus is seen extensively involved by a new formation. There are two false points of motion—one just below the insertion of the deltoid, and another in the surgical neck. Tumor-tissue is seen distinctly in these locations at the expense of the bone. The muscles covering the front of the arm were in part invaded by the tumor, which in its invasion of healthy tissues followed the planes of the fibrous tissue between the muscle-bundles. Microscopically, it is a typical carcinoma."

Dr. MARKOE said he had presented this case more especially to have an opportunity to say a word about a method of managing surgical wounds which had given him great satisfaction, and which he believed had not been so extensively recognized as it deserved to be. Surgeons had for years used capillary drains in the shape of horse-hair, in the olden times silk, and more recently the catgut leash, yet he believed that very few surgeons had much confidence in the method for large wounds, as it had been used commonly for small ones, and particularly for those of the scalp—a single thread or two of catgut being placed in the wound as a drain, the wounds thus treated doing extremely well. But a good many surgeons abroad, and some here, had used the method in the treatment of larger wounds, and had found it satisfactory. He had himself felt that the method had certain advantages which were worthy of attention. In the first place, it exerted a positive force in drawing out from the cavity of the wound any fluids which might be retained there. If the drain was in a dependent position, the capillary force exerted by the leash would be almost as powerful as that of a siphon. The moment it was applied it would be seen that drainage commenced, taking place along the sides and between the strands of catgut. The other features of the dressing perhaps presented nothing unusual, careful apposition being very important. Iodoform and bichloride gauze with borated cotton externally completed the dressing. Dr. Markoe then related some cases showing the advantages possessed by this form of drainage.

On June 18th he extirpated a recurrent tumor of the breast which had been removed about a year before. The axillary glands were very extensively involved, and this rendered free evacuation of that region necessary—so free that the sterno-clavicular articulation was felt with the finger during the operation. The wound was a very large one, and was drained with two capillary drains, each composed of six or eight strands, tied in the middle, the knot being then thrust into the deeper part of the wound. The double leash of threads projected from the wound about an inch. One of these drains was placed in the lower and the other in the upper angle of the wound. The

wound was brought together with catgut stitches dressed with iodoform and bichloride gauze, and covered over with cotton. The dressing was left on fourteen days, at the end of which time the wound was found to be perfectly healed from end to end. The finger, passed over the line of union, rubbed away the projecting strands of the drains and the unbared parts of the sutures. Not a drop of pus had formed, and the wound was so absolutely and soundly healed that no further dressing was applied.

On September 23d he operated in another case for relapsing cancer of the breast, making a smaller wound and not opening the axilla, but applying the same kind of dressing. On the ninth day the wound was found to have healed perfectly.

September 24th he removed a cancerous breast of moderate size, in which a few of the axillary glands were involved, making a long incision necessary for their complete removal. The capillary drains were inserted, and on October 9th, the fifteenth day, when the dressing was removed for the first time, the wound was found to be completely healed without any formation of pus.

On the 25th of September he removed at the shoulder joint the arm which had been shown to-night. Two catgut drains were used, with the usual dressing. The gentleman under whose charge the patient was removed the dressing a little early—only thirteen days after the operation. In that case the wound was found to have healed perfectly except a little strip at one angle, at which there had not been perfect coaptation of the flaps. The wound, however, was very superficial, and, doubtless, would heal under another dressing.

On October 12th he performed another breast amputation, applying a similar dressing, and the wound had now completely healed except at one point, at which a clot of blood had rested between the lips of the wound.

He made these statements because, so far as his experience with this method had extended, it had led him to have the greatest confidence in it, and, while he did not maintain that it was applicable to all wounds, yet in those cases in which it was possible to obtain primary union he believed it to be better than any other form of drainage. The ordinary India-rubber drainage-tube certainly always left a fistula. Neuber's tube, while it often acted well, securing perfect healing of the wound nearly throughout, still left one point open, and sometimes acted as a foreign body.

Dr. STIMSON inquired what kind of antiseptics had been employed.

Dr. MARKOE replied, The bichloride solution, and iodoform to the wound surface. The drainage-tubes were prepared in oil of juniper, after Kocher's method.

Dr. JAMES L. LITTLE had had considerable experience with this form of drainage, applying the strands of catgut in the manner described by Dr. Markoe, and it had given entire satisfaction. He had not used it extensively in large wounds.

The PRESIDENT had used the capillary drains, both of hair and of catgut, and, so long as the wound was fresh and the discharge serous, the capillary action had done well; but, so soon as the secretions became thick, it had not worked; the strands became glued together and the capillary action ceased. He knew this to have been the experience of many other surgeons also. He had employed the method in large wounds, as in breast amputations, and certainly had not been so well satisfied with it as with the rubber or bone drain. He wished to state, but not too positively, that he had some doubts even in regard to the bone drainage-tube. In one case recently in which the bone drainage-tube was employed, a septic condition developed, and he was strongly of the impression that it was due to the absorption of the softened bone. This was not a single instance,

and from such cases he had learned to place more reliance upon the rubber drainage-tube than upon any other, although he recognized its great disadvantage in having to be removed from four to seven days after the operation, but by this time the risk of inflammatory reaction had pretty well passed. At any rate, he had not found any material risk to the patient from changing the dressing at that time and putting on the permanent one.

Dr. WILLIAM S. HALSTED thought that it would be difficult in a given case to know just what to attribute a bad result to, with the imperfect antiseptic technique at present existing even in our best New York hospitals. Trained nurses, with long sleeves and hands uninspected, were allowed to pass and hold dry sponges. He had repeatedly observed ligatures handed to the operator from the mouth of the interne, and seldom failed to find instruments, especially artery-clamps, which had been insufficiently cleaned. He observed further that in some of the hospitals the preparation of the catgut was intrusted to the apothecary, and, even if it was prepared by the interne, it would not be a guarantee that it was properly, even if conscientiously, done.

The PRESIDENT said that we all recognized that there were numerous sources of septic infection, and to these he had directed special attention in a paper read last year. He now only spoke of the possible risk of infection from the bone drain, because it was subject to animal decomposition. The early ones, kept in carbolic oil, softened notably in a few months—sustaining the view of the non-aseptic condition of the oil. Lately the bone drains had been kept in alcohol, pure or mixed with bichloride of mercury. These were harder and lasted longer.

Dr. MARKOE said his object was to secure union without any suppuration, and, if the catgut drainage did not prevent it, we were still in the same position as if the rubber tube had been employed, and the permanent dressing might be applied in the same way. But he believed that the capillary drain gave a much better chance for primary union, and it was very desirable, if possible, to secure that result.

Dr. HENRY B. SANDS thought the cases reported by Dr. Markoe afforded a striking illustration of the advantages of a dressing which offered no obstacle to union by first intention. He believed that, had the rubber drain been employed, the excellent results reported could not have been obtained. There certainly would have remained for a time a granulating, if not a suppurating, tract along the course of the drainage-tube. He should say that, if it was probable that a wound would heal only by granulation, it would be desirable to use a rubber drain, but, if the case was one in which primary union might be anticipated, a soluble drain would be preferable. He did not feel quite certain as to the capillary action of the catgut drain. According to his experience, after it had been in place a short time, it became quite soft, the separate strands became agglutinated to one another, and capillary action was diminished or arrested. Regarding the comparative value of this and the decalcified-bone drainage-tube, he doubted whether the former possessed any superiority. He had obtained absolutely perfect primary union in amputation of the breast in a number of cases in which he had employed the decalcified-bone drain. He did not believe, however, that union without suppuration could be accomplished unless great pains were taken to secure perfect coaptation, not only of the edges, but also of the deeper surfaces of the wound. He should not expect to get union with any form of drainage, however perfect, if the surfaces of the wound were not in perfect contact.

Dr. LITTLE had operated in a case of cancer of the breast on Saturday morning. Four days previously, and this morning, the temperature being markedly elevated, he removed the dress-

ing, and found that the drainage had been imperfect, owing to the fact that the bone drainage-tube had collapsed and become occluded. He had known this accident occur in several cases after the use of the bone brain. He inquired of the president whether the preparation of the tube had anything to do with its remaining patent.

The PRESIDENT had found that tubes prepared after the manner recommended by Neuber, in carbolized oil, were fragile; a needle passed through the end of them would cause them to split, and by the third or fourth day they would sometimes be found collapsed, and would fail to act as drains. If kept in glycerin and alcohol, after Kocher's method, they would not split, and were more readily soluble; the ends would be found almost wholly absorbed within three or four days. If put in bichloride solution and alcohol, they lasted as long as from five to seven days.

Dr. SANDS said the bone drainage-tubes which he employed were prepared according to a method suggested by the apothecary of the Roosevelt Hospital. The oil was extracted by means of chloroform, and the tubes were afterward kept in alcohol. They were firm, and did not collapse so readily as when kept in carbolized oil.

Two Drainage-Tubes in the Pleural Cavity Eighteen Months.—Dr. LITTLE presented two rubber drainage-tubes, three eighths of an inch in diameter—one eleven and a half inches, and the other nine inches in length—which he had removed from the pleural cavity of a man the day before. The patient was thirty years of age, and was operated upon in April, 1883, by Dr. Burchard, for empyema of the left side. An incision about two inches in length was made through the eighth intercostal space, and eleven quarts of pus were evacuated. The drainage-tubes were then introduced, and the extremities made fast by ligatures fastened to strips of adhesive plaster. The next day it was found that the adhesive plaster had become softened by the discharges, and the tubes had disappeared. The surgeon in attendance searched for nearly two hours without finding them. A consultation was held the next day, and it was decided that, as the patient was doing well and the cavity was so large, it was best not to make further search until the cavity had contracted. Two months afterward the patient passed from under the doctor's care. When he presented himself to Dr. Little, eighteen months after the first operation, the daily discharge of pus from the wound was seven or eight ounces. On introducing the probe, it was thought it came in contact with a tube. About an inch of the ninth rib was excised, and the drainage-tubes were removed with the forceps without difficulty. The question naturally arose, What was the best way to fix the tubes? Dr. Little had been of the impression that it consisted in passing a safety-pin through the end of the tube, but at the operation in this case a physician told him he had once had the pin cut through and the tube fall into the pleural cavity. Fortunately, however, he was able to pick it out with the forceps.

Dr. MARKOE remarked that the system of through-drainage which he employed offered a certain amount of security against the tube escaping into the pleural cavity: at any rate, the accident had never occurred in any of his cases.

Dr. STIMSON, in reply to a question by the president, said he had once had occasion to remove a drainage-tube about one inch long from the pleural cavity, into which it had slipped after the breaking of the string by which it was secured. He removed a portion of one rib and seized the tube with a long forceps.

Dr. LITTLE referred to the manner of avoiding hemorrhage from the intercostal artery in this operation by adopting the procedure recommended by Dr. Abbe. He exposed the rib and cut it away with the bone-forceps. He then passed a double

ligature with an aneurysm-needle behind the rib, including the vessel, periosteum, and pleura, tied in two places, and cut between, thus avoiding all hemorrhage.

Dr. HALSTED had been surprised to see how little the intercostal arteries bled in cases of empyema of long duration. He had within a few months performed two extensive thoracoplasty operations. In the one case large portions of six, and in the other of eight, ribs were removed as well as the subjacent parietal pleura, and, to the best of his recollection, he had found it necessary to ligate but one intercostal artery.

Dr. MARKOE did not believe the costal artery was wounded in this operation, but thought it was pushed aside and left in contact with the pleura.

The PRESIDENT referred to a case in which the drainage-tube escaped into the pleural cavity, and he was enabled to remove it by enlarging the original incision.

Dr. SANDS had been enabled to prevent escape of the drainage-tube into the pleural cavity by making use of a tube with a flange, like the ordinary tracheotomy-tube. The short tube fulfilled all indications, and could be used without danger.

Dr. LITTLE said it had been suggested to divide the end of the tube into slips, then sew on strips of rubber cloth, and tie around the body, as described by Dr. Pilcher in his book on "The Treatment of Wounds."

Dr. CHARLES K. BRIDGON believed the tube entered the cavity by the act of inspiration. Frankel had recommended a metallic tube with a flange, but longer than the one employed by Dr. Sands. A double tube had been recommended—one for pumping in liquid, the other to allow it to escape.

Hysterectomy for Multiple Fibromata.—Dr. STIMSON presented a uterus with its appendages, which he had removed by abdominal section from a woman, forty-five years of age, for multiple fibromata. The mass, which was about six inches in diameter, was raised, the cervix transected with an ivory pin carrying a double elastic ligature, and each ligature was made to embrace half of the cervix and the corresponding broad ligament. The mass was then cut off above. There was no hemorrhage. The pedicle was treated by the extra-peritoneal method. The patient made a good recovery. Dr. Stimson had done a similar operation in a case reported to the society at its last meeting in May of this year, the patient making a good recovery.

Dr. LANGE said that he had taken the precaution, before applying the elastic ligature to the pedicle, to constrict the parts with the écarosse lest the ligature might fail to compress the thick mass sufficiently to prevent hemorrhage. He had always adopted the intra-peritoneal method of treating the pedicle, securing the ligature with a lead ring, cutting the tumor off immediately above it, and he had not found any trouble from the presence of the clamp or ligature in the abdominal cavity. Only a few days ago he had removed the uterus for a large myoma, after this method, in a case in which he had originally intended to do simply Tait's operation on account of the low condition of the patient, but, being unable to get at the second ovary, he removed the whole mass, and the patient was now doing very well.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Meeting of September 16, 1884.

The President, Dr. J. A. MCCORKLE, in the chair;

Dr. Z. T. EMERY, Secretary.

Antiseptics in Midwifery.—Dr. CHARLES JEWETT read a paper with this title. [See page 481.]

Normal Parturition always Physiological was the title of a paper read by Dr. ERNEST PALMER. [See page 483.]

Injuries to the Pelvic Floor.—Dr. ALEXANDER J. C. SKENE read a paper on this subject. [Dr. Skene's paper will be published in a subsequent issue of the journal.]

Dr. WIGHT hesitated to appear in the debate under the circumstances, as he did not profess to be an obstetrician. Yet he might be permitted to say something in regard to the subject of antiseptics, or what related to it, perhaps. He thought we might put above all other propositions this: That antiseptics was a work in itself, *per se*, to be done; and, having come to that point, we should find it expedient to make another remark; and that was, that we might find all these gentlemen differing in the plan which they adopted in carrying out the work of antiseptics. He had so often been heard upon this subject that he would not reiterate what he had said over and over again, but he would make a statement at the outset in that respect. He desired to say a word or two with reference to the kind of antiseptic work which he had practiced in reference to cases of midwifery. He had attended a few cases in his career, which had covered several years, and he wished to say that he had never lost a patient by puerperal fever. He had seen patients who had had it, and been attended by midwives, who had died, but none of his patients had died. He did lose a puerperal patient once, but that was the result of neglect on the part of her husband. He would not or did not provide for her fire or food. He killed her instead of the doctor. The doctor could not save the patient. She died from shock—not from puerperal sepsis. He had never used the vaginal douche at any time upon puerperal patients. He attended these cases some years ago—ten or fifteen a month—but not many now. After the patient had been confined, he kept her scrupulously clean. He used alcohol and water as a wash, externally, but never used an internal vaginal application. More than that, as soon as his patient was confined he gave her a good large milk-punch, as she was in an exhausted condition, and it did her good, always. It was said such measures ought not to be practiced; he did it nevertheless. Then he gave her five grains of quinine in the morning and five grains in the evening. He fed her liberally, and she did well. He never deviated from that practice, and never would so long as it carried him through safely, and nothing had delighted him more than to listen to the sentiments expressed in the papers which had been read. In 1870 he attended a patient in her second confinement. He had also attended her in her first confinement. Her oldest child was born about twenty months before the second. She was confined in a small room. About twenty hours after confinement the oldest child broke out with malignant scarlet fever, and in about thirty hours more it died. This woman got out of her bed, went to the carriage, in the rain and hail and snow, walked to the grave, stood upon the ground a half-hour, returned home, and went to bed; and she did the best of any confinement patient he ever had. In the spring of 1884 he attended a woman who had an ordinary normal labor, although a pretty severe one. Her oldest child, about six years of age, had a severe attack of scarlet fever. The day after she was confined the boy was put in the same room with the mother. He had a temperature of 105°, but there was no rise of temperature in the mother from the beginning to the end of her sickness. He mentioned these cases as a curiosity, for he had been taught that scarlet fever would produce puerperal fever if brought near a woman while in the puerperal condition.

Dr. OTTERSON spoke of the necessity of cleanliness as a preventive of the necessity of using antiseptics. He did not recollect more than eight or nine cases of puerperal fever in his experience in more than three thousand confinements. Some of these cases could not be traced to any special cause. One could be traced directly to shock; another was brought on by

a violent fit of temper, followed by delirium and exposure, with fatal results. All the other cases of which he had any recollection occurred without any special known cause. Only five cases in his practice had been fatal, and one case he could trace directly to a septic condition. He would disinfect the rooms and surroundings of patients, and be more careful to prevent its necessity. Much might be conveyed by the old saying, "meddlesome midwifery is bad."

Dr. THAYER said his obstetric practice was not sufficiently large to make it worth while to relate his experience. During the last eight or ten years he had always used the vaginal douche during the continuance of the lochia without having produced any ill effects that he was aware of. Some of the papers read before the Academy of Medicine within the last year made it appear that cases have done better without the use of this measure, and he had noticed that Dr. Thomas had concluded to restrict the use of it in future. The speaker was inclined to follow the same course. He was brought up with the same feeling that Dr. Otterson had expressed—that meddlesome midwifery was bad, that the process was a physiological one, and the best plan was to trust entirely to nature, unless there was occasion for interference. His practice had been to follow this plan, with the single exception which had been mentioned, of using the carbolic-acid or boric-acid solution after labor. He had never lost a patient from puerperal fever. He once lost a patient after craniotomy within three or four days after confinement, but he had had no severe cases of puerperal fever. He was of the opinion that the tendency to follow out these extreme measures of practice by specialists should be restrained. He believed most heartily in the young men of the profession. He went to them for advice. He believed in the constant advancement of science; and yet he believed, also, that some specialists were pushing measures beyond their legitimate bounds. He thought the remarks here to-night of a precautionary character were very desirable and appropriate.

Dr. WALLACE had records of over seventeen hundred cases of confinement. Among these there had been four cases of puerperal fever, none of which proved fatal. In only one of these was a vaginal injection used. He had never practiced the use of antiseptics in obstetrics, as he had never found the necessity for anything of the kind.

Dr. WALKER asked Dr. Jewett whether this plan of using iodoform was one which had been devised by himself, and whether he had come to the conclusion that the use of iodoform and the other materials which he had mentioned had done any good or harm.

Dr. JEWETT replied that the use of iodoform was not original with himself. It had been used more or less in obstetric practice for several years. While he thought injections very capable of doing mischief, especially in the hands of the average nurse, he had no reason to think they had done harm in his hospital practice. The point he wished to make was, that in his experience they had failed of their mission.

Dr. SKENE remarked that the subject under discussion was certainly one of very great interest, because of the fatal character of puerperal fever and because of the question of preventability. There was also another source of interest in the fact that there was so little known about it positively. Certainly there had been much discussion on the subject in recent days, and yet, throughout it all, there was a great lack of anything like definite knowledge in that which had been said and written. It was true that we had positive statements in relation thereto, but they were not all sustained by positive knowledge. Opinions might be stated very positively without being based upon any very good ground, hence he was disposed to look for facts rather than propound theories. It seemed to him that the all-

important question brought up by the papers read was, had we, in the various forms of childbed fever, any more than puerperal septicæmia? He had always believed that we had an undoubted puerperal septicæmia, but he also believed that there was a puerperal fever characterized by peritonitis, etc., which was not a simple surgical septicæmia. There had been a tendency lately to overthrow that doctrine, but he was as firm in that belief as ever—not because he could prove his position, but because the facts had not been all accounted for by those who doubted it. He believed that puerperal septicæmia was largely preventable, and hence he indorsed anything and everything that could be done in the way of preventing it by care, cleanliness, and antiseptics. Then the question as to the management of septicæmia after it was established arose. We had been led to believe that, if due care was taken to prevent it, little danger of getting it need be apprehended, and, if it was established, it was in many cases easily controlled, and yet we saw how absolutely the most approved means failed to arrest the disease in many cases recorded in the paper just read. Certainly, so far as his experience went, it showed the same thing—that all known means employed to control puerperal septicæmia would fail in a great number of cases, while in a lesser number the treatment was efficient. This difference in the efficacy of treatment might be due to the fact that there were two forms of septicæmia—i. e., the disease behaved in two different ways. In the one form the general system was repeatedly or continuously poisoned by absorption from a dépôt in the genital tract where suppuration or decomposition was going on. If the point of supply could be reached and thoroughly cleansed and kept clean, the general septicæmia disappeared at once. In the other form the system became poisoned, apparently from a like source, but the septicæmia continued, and sometimes grew in violence after all local trouble had been removed. In the worst case of puerperal septicæmia that he had ever seen end in recovery the patient had at times a temperature of 105°, while the pelvic organs were all perfectly normal, no trace of disease or injury being found. One variety was controlled easily if we could reach the original point of infectious supply. The other seemed to be wholly beyond the control of the obstetrician. A celebrated surgeon had said he did not know what to do with septicæmia. He knew many things to do to prevent it, but, when once established, he did not know anything that had any influence in curing it. Such a statement would apply undoubtedly to the latter form of septicæmia. He believed that there was something else than septicæmia in some puerperal fevers. He thought we had a puerperal fever, characterized usually by peritonitis, which was due to zymotic causes, and was related more closely to the zymotic class of diseases than to septicæmia of traumatic origin.

This zymotic form of fever had a clinical history more closely related to diphtheria and scarlatina than to ordinary surgical septicæmia. If this idea was correct regarding the existence of a zymotic infectious puerperal fever, then it was possible that the popular views of antiseptic means of prevention and treatment were not in advance of the older way, which was for the doctor who found himself in an epidemic of puerperal fever to retire from obstetric practice for a time. At any rate, it was unsafe to rest secure (with our present knowledge) upon the power of disinfectants. They might and did guard against septicæmia, but they were not a safeguard against all infection. We were still in need of more facts regarding the infection and contagion of puerperal fever and the boundary-line between these two forms of septicæmia before we could definitely formulate our ideas regarding their prevention and treatment. He was satisfied practically that it was dangerous, or at least useless, to interfere with the patient immediately before and

after parturition if there was no apparent trouble. He would say it was better to let well enough alone. So long as the patient was doing well, she should be let alone, so far as local treatment was concerned; but, so soon as she manifested any evidence of disturbance, it was always deemed wise to ascertain if there were any local causes, such as any accumulated foreign decomposing or festering substance in any part of the genital tract, and it should be removed. The question yet remained in a somewhat unsettled state as to how far we could prevent septic trouble. Of course, a great deal could be done by way of cleanliness on the part of the obstetrician and nurse or attendants; but how far we could control atmospheric influences was not yet clearly pointed out. We had a great field for investigation in that line. If we rested assured that we could control septicæmia with our present knowledge of the subject without further investigation, we were simply stumbling-blocks in our own way, and in the way of the welfare of our patients. The two papers just read were evidences of work in the right direction. They gave carefully made clinical observations and the facts obtained thereby—just what was needed. These facts appeared to be slightly opposed to some of the theories in vogue. So far as that was the case, we were nearer to the solution of the problem. In the past, theories had been made first, and the facts made to fit them; at the present time we found out facts and made our theories out of them.

THE NATIONAL CONFERENCE OF STATE BOARDS OF HEALTH.

First Annual Meeting, held in St. Louis, Monday and Tuesday, October 13 and 14, 1884.

Monday's Proceedings.

Mr. ERASTUS BROOKS, of New York, in the chair.

The Chairman's Introductory Remarks.—After calling the meeting to order, in Liederkranz Hall, the CHAIRMAN congratulated those present on the good attendance, which intimated that a proper interest in health questions was felt in the several bodies they represented. It would be idle words were he to repeat what had been said in the past with regard to the importance of organizing State boards of health. He was glad to know that in nearly every State there were such boards, and that the few States which were unrepresented at the present time were sufficient promise that there was a future with regard to that great question which would find every State and territory fully organized. In his own State, he was happy to say, local organizations have been completed in 900 towns, in nearly every one of the 240 villages, and in 24 cities. What had been accomplished they had been enabled to do rather by persuasion than by force or coercion, since the State gave them unlimited power to establish organizations in the various towns and villages.

A Proposed Plan of Organization.—The minutes of the preliminary meeting, held in Washington, May 7th, having been read by the Secretary, Dr. J. N. McCormick, and accepted, Dr. HEWITT, of Red Wing, Minn., presented a plan of organization, in behalf of the State of Minnesota. The main points were as follows: The establishment of a body to be known as the Council of State Boards of Health of the United States, the officers to consist of a chairman, a corresponding secretary, a recording secretary, a treasurer, and an executive committee, the latter to consist of one member from each State board. The objects of the organization were to be, to cultivate a closer acquaintance between officers and members, to facilitate discussions of sanitary work, and to give better opportunities for comparing and discussing methods.

On motion, the matter was referred to a committee consisting of the chairman, the secretary, and Dr. Rauch, Dr. Hunt, and Dr. Hewitt.

A Communication from the American Public Health Association was received, inviting the members of the conference to attend the meeting of the association, and to read papers. The invitation was accepted with thanks, but the feeling was very generally expressed that the work of the two bodies should be kept distinct. Dr. RAUCH said he proposed to deal with the men who were to give orders when the cholera came, and not with those who would only hold "sanitary prayer-meetings."

State Rights and Sanitation.—Dr. J. H. RAUCH, of Springfield, Ill., read a well-written argument on the cholera question, in which he discussed the efficacy of quarantine and the rights of a State to preserve its own territory free from contagion. Illinois was vitally interested in the manner in which quarantine was enforced in New York and Eastern ports. His experience in cholera epidemics had convinced him that cholera was conveyed only by means of infected persons, and hence there was no necessity for guarding against merchandise, rags, etc. The Illinois State Board of Health would have the right to close up the Illinois end of the St. Louis bridge if the great city became plague-stricken. The State would also have the right to stop the Great Canada Southern railroad from entering the State territory if the authorities thought Canada was afflicted with cholera. The same could be done on all lines, and all States had the same power—it was a mere question of assertion. For a period of six years sanitary officers and sanitary authorities have had no great demand made upon them. During these six years the interest in sanitary matters raised by the epidemic of 1878—the yellow fever epidemic—had gradually diminished and had been displaced by other matters of interest. When an epidemic actually existed and industry and commerce were paralyzed, there was no question in the public mind as to the desirability of sanitation, no hesitancy in making appropriations. But Rabelais had told us, nearly four hundred years ago, what the devil did when he got well. The Forty-eighth Congress adjourned in spite of the fact that an epidemic was staring us in the face, after rendering inoperative all previous legislation on sanitary matters. It was now our imperative duty as sanitary officers to awaken public interest and to prevent the introduction of the epidemic of Asia to our shores. Much had already been done by the action of national and State authorities, and since the second of July last over sixteen States have issued circulars of admonition.

Congress should be urged to reorganize and rehabilitate the National Board of Health, or to provide an efficient substitute—one clothed with increased power and supplied with ample funds to maintain an effective system of modern sanitary quarantine for the exterior; to maintain an interior sanitary inspection service for the great highways of travel by rail and river; and to give judicious co-operation and substantial assistance to States and municipalities in preventing the introduction of epidemic diseases into one State from another, and their spread within the States themselves. Congress should give the President the power to issue a proclamation upon the recommendation of the national health authority, forbidding immigration into the United States from infected districts; and it should provide some method of international sanitary co-operation between this country and the Dominion of Canada, whose interests were substantially the same as ours in these matters, and whose contiguity made co-operation of vital importance. In States which now had no boards of health, or whose boards were not provided with adequate resources, the people should be awakened to the necessities of the situation. Legislators should be thoroughly informed as to the facts, and urged to provide suitable legislation. Informa-

tion on sanitary matters should be widely diffused to this end, and also to the end that, if an epidemic should come, we might not have to encounter the obstacles which ignorance was always ready to put in the way of what it did not understand. Happily, in this country, we were not likely to meet with the treatment that the superstitious peasantry of France and the lazzaroni of Italy had accorded their physicians and health officers. But sanitary education and knowledge could not be too widespread. He would suggest that when this meeting adjourn it should adjourn to meet again in Washington in December for the purpose of conferring with the President, the cabinet officers, and the committees of the Senate and House, as to the legislation which should be asked for at the next session of Congress. To this meeting not only should representatives of State boards of health be invited, but also all quarantine officers and health authorities of all the large cities, as well as those of the Dominion of Canada.

The National Board of Health.—Dr. CHARLES SMART, of the army, read a paper outlining the method of disinfection and quarantine used by the national board. The board based its rules and regulations to prevent the introduction of cholera into the United States and its spread from one State to another upon certain incontrovertible facts demonstrated by science and experience. Cholera was caused by a specific germ, and this germ could be destroyed with no other interruption to travel and traffic than was needful to discover its presence and apply the necessary means for disinfection. In order to secure international co-operation a conference had been held, and, of twenty-seven nationalities represented, the larger number were prepared to enter into a joint treaty that would secure harmony of action. The first step taken by the national board was to frame rules and regulations to be enforced at foreign ports to secure the best sanitary condition of vessels about to leave for a port of the United States. Ships were the great carriers and propagators of diseases of foreign origin, and the modern emigrant ship was a vast field for the cultivation of pestilence. Sanitary service at sea, for securing at the foreign port a clean vessel and uninfected freight, had also commanded the attention of the board. On the arrival of vessels at any port of the United States, proper steps were laid down by the board for the prevention of the entry of any infected material. Every vessel was visited by the quarantine officers, and all needful precautions were taken in case of suspicion of pestilence; clothing, baggage, and cargo were carefully disinfected. If, in spite of all these precautions, the disease effected an entrance into any port, measures were taken to prevent its spreading from that port to other ports on the coast, or to interior points. Seacoast, river, and railroad travel, and transportation were conducted under sanitary supervision. In the case of coast or river steamboats or vessels sailing from the infected port, measures of inspection and disinfection were enforced similar to those practiced with regard to vessels from foreign infected ports. In addition to this, inspection-stations were established at certain points on the Mississippi River, the medical officers of which acted as quarantine officers for the States threatened with invasion. The reader mentioned some additional recommendations for the establishment of a more rigid local quarantine.

Dr. BAKER, of Lansing, Mich., then moved that all papers read be referred to a special committee of five for consideration. The motion prevailed, and the chair appointed as such committee Dr. Baker, Dr. Rauch, Dr. Walcott, Dr. Bryce, and Dr. Herrick.

The CHAIRMAN opened the discussion on the two papers with a warm defense of the sanitary officers of the State of New York. So far as was possible, they had done everything to pre-

vent the introduction of cholera into the country by way of New York, and what they had done had been well done. Indeed, their arrangements were so complete that, in his opinion, it was almost impossible for the disease to effect an entrance into New York.

The papers were further discussed by Dr. J. B. LINDSLEY, of Nashville, Tenn., and Dr. C. W. GOVERTON, of the Dominion of Canada.

Tuesday's Proceedings.

Can Epidemics be excluded by Sanitary Cordons?—This was the title of a paper read by Dr. C. W. CHANCELLOR, of Baltimore. He desired to present a few facts in regard to the spread of cholera, with a view of arriving at some conclusion in regard to its prevention. He dwelt upon the folly of maintaining a system of quarantine while strictly sanitary measures were neglected. The quarantine theory demanded the exclusion of the germ of the disease, and quarantine was utterly useless to effect this, and always injurious, not only to commerce, but by inducing a condition of the public mind such as the panic recently witnessed in the south of France and Italy. Sanitary cordons failed to exclude cholera in 1823 at Moscow, Berlin, Vienna, Hamburg, Paris, Cairo, and Alexandria. It had been shown by reference to the outbreak of cholera in those places that the disease first appeared in places where the atmosphere was in a vitiated condition, and that the contagion was not communicated from other infected cities. While the promised restriction of cholera by quarantine had never been secured, the interference of governments—municipal, State, and national—could be exerted in such a manner as to disarm the disease of much of its malignity and prevent its extensive spread among us. This might be done by establishing at home, and without delay, an enlightened system of sanitary police; by taking effective measures to insure the cleanliness and proper ventilation of our cities and their suburbs; by impressing upon every class the importance of temperance, and especially of abstinence from every species of unwholesome food or intoxicating drinks, and withal by endeavoring continually, instead of exciting unnecessary alarm, to tranquilize and strengthen the public mind and to inspire confidence in all classes of citizens.

It was voted to hold the next meeting of the conference in Washington, on the second Tuesday in December.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Twelfth Annual Meeting, held in St. Louis, Tuesday, Wednesday, Thursday, and Friday, October 14, 15, 16, and 17, 1884.

The President, Dr. ALBERT L. GIBSON, of the navy, in the chair.

Tuesday's Proceedings.

A Plan of Permanent Organization was reported by Dr. CHARLES SMART, of the army, on behalf of the Sub-committee on Incorporation. The plan was to organize under the laws of the District of Columbia, which required that twelve of the members should reside in the District. It was voted to adopt the plan recommended in the report.

The Squalid Dwellings of the Poor; a Social and Sanitary Reproach.—After the transaction of some routine business, including the election of a large number of new members, Dr. CHARLES W. CHANCELLOR, of Baltimore, read a paper with this title. He had selected the subject on account of its transcendent importance at this time, and he proposed to discuss it from both a social and a sanitary point of view. If investigation should be carried on and a report made on the dwellings of the poor in our cities, it would reveal fearful degradation and vice. Public inquiry would reveal places where decency was a

physical impossibility, and where men, women, and children were schooled in vice. At times whole streets were blockaded against the police. Over Saturday and Sunday the inhabitants of these rookeries gave themselves up to debaucheries of all kinds. If we turned our eyes to the difficulties in our own country, we were at once impressed with the melancholy conviction how little had yet been done to improve the human race. The poorest individuals were the most intemperate, but there was really no *a priori* cause why the poor should be addicted to drink unless it was the sense of their own misery. There were two primary and fundamental considerations upon which a nation must depend: First, health; second, education. Therefore, let no government be without a health department, presided over by health officers whose duty it should be to enforce wise laws. A nation such as ours, of fifty-five millions, with vast manufacturing industries, and a great commerce to attract the attention of our people, could not afford to waste the lives of its citizens. Disease paralyzed labor and wasted capital; it should, therefore, be the primary object of a humane government to prevent disease. Never before was the misery of the poor man more pressing or his daily life more degraded than at the present time; and here was a boundless field for philanthropists. The streets and alleys of our crowded cities furnished examples of squalid misery which were the disgrace of our civilization. It was here that the fevers were to be found that caused the deaths that figured so largely in official reports. Here people were absolutely ravaged by fever, living and dying amid terrible squalor. The atmosphere was foul in the extreme, and, unless one had a strong stomach, it was difficult to remain in the houses over a minute. Landlords, when their property was declared a nuisance and condemned, exacted from the cities an exorbitant value for the condemned property. The remedy for all these evils lay in the proper enforcement of rigid sanitary laws.

The Hygiene of the Habitations of the Poor was the title of the next paper, read by Major SAMUEL A. ROBINSON, of Washington, who depicted the errors of the construction of the habitations of the poor—errors that had been the fruitful cause of many diseases. But improvements should not be made at the expense of the poor, nor should they be forced to stand the cost of untried innovations. The reader showed how drains could best be used, and discussed the general negligence displayed by the poor of all cities in carrying off the refuse and garbage. It was a mistake to make the poor pay for the removal of this offal, as they often adopted all kinds of tricks to escape the necessity of undergoing this expense. Houses that were unwholesome should be torn down, and experience taught us that where this had been done new and good houses had been erected in their place. Model houses were those which were light, airy, and clean, and had facilities for the removal of refuse, and until we had such houses the schoolmaster and minister would labor in vain, for degradation and disease produced crime. It was a good home that made a good man.

The Sanitary Survey of a House.—A paper with this title, by Dr. WILLIAM K. NEWTON, of Paterson, N. J., was a narration of the method in vogue in that city for the determination of the relative sanitary qualities of any house. Health officers were given blanks on which certain questions and directions were printed, giving the necessary qualifications of a perfect house. The degree of sanitary excellence was made up from the reports of officers, who crossed off the qualities a building did not possess, and allowed those it did to remain. The first thing to be considered was the street on which the house was situated. Was it made allowing a free current of air to circulate, or narrow; well kept, or in bad condition; clean, or dirty? How were the streets paved? Which way did the house face—north, south,

east, or west? Were there trees in front of the house? Trees would be a blessing in a wide street, tempering the rays of the sun, but in a narrow street they would cause disease by obstructing the rays of the sun and making the front rooms damp and unwholesome. The next point of interest was the yard. It was noted whether garbage was allowed to accumulate; the water supply was examined, and it was ascertained whether there were any sources of contamination; whether domestic animals were allowed in the yard. Then the inspector went into the house, visited the cellar, and noted whether the foundation was of stone, brick, or rubble. The ventilation of a house, method of heating, plumbing (especially leaks in the same), should all be examined carefully. The population of a house, the number of families living in it, the number in each family, the number above five years of age, and the number of rooms to each family, were very important data.

The three papers were discussed by Dr. EZRA M. HUNT, of Trenton, N. J.; Dr. HOMER A. JOHNSON, of Chicago; Major ROBINSON and Mr. ERASTUS BROOKS, of New York; Dr. B. HARVEY REED, of Mansfield, O.; Dr. A. N. BELL, of New York; Dr. JOHN FEE, of Kansas City, Mo.; Dr. J. H. RAYMOND, of Brooklyn; Dr. BRIGGS, of St. Louis; Dr. GUSTAVE DEVERON, of New Orleans; Dr. P. H. BRYCE, of Toronto, and Dr. COOK, of Nashville.

The Hygiene of Occupations was the title of the next paper, by Dr. GEORGE H. ROSE, of Baltimore. He prefaced his remarks by alluding to the paucity of literature and statistics with reference to the subject, and then proceeded to deal with the statistics on the subject prepared at the instance of the Massachusetts Legislature, which covered the period between May 1, 1843, and December 31, 1874. The figures showed that cultivators of the soil and brain-workers had a good expectation for long life. Those engaged in the manufacture of chlorinated lime were subject to chronic chlorine poisoning. Persons engaged in the vulcanization of India-rubber were very much troubled with pneumonia, and had a predisposition to rapidly succumb to consumption. Lead-workers suffered from poisoning, and painters were especially liable to the same disease. Mirror-makers, fulminate-makers, batters, and others inhaling dust were liable to consumption, and brass-workers to a peculiar disease termed brass-founders' ague. Stonecutters in Germany lived to the average age of 36 3-100 years, but the figures showed that in this country the average length of life was 40 90-100 years. Rag- and wool-sorters were liable to a peculiar disease, which was probably anthrax. The average life of millers, according to Hirt, was 45 1-10, but according to the Massachusetts figures, 57 14-100. Workmen in grain-elevators suffered from catarrh, and brush-makers were peculiarly liable to phthisis. Firemen on steamers suffered from pulmonary diseases and from heart disease. Statistics showed that brain-workers had a higher expectation of life than any class of men. In conclusion, he suggested that the association should appoint a committee to consider the question of the effects on health of the various avocations, and that each member should give the result of his researches at their annual meetings.

Protective Spectacles for Workmen.—In a paper with this title, Dr. ADOLPH ALT, of St. Louis, adverted to the dangers to the eyesight which attended work in foundries, stone-yards, and other places in which hard chips were constantly flying about, and to the loss of the sight of both eyes in consequence of sympathetic ophthalmia arising from injury to one eye. The all-important object, he contended, was to protect the eye and prevent accidents. For that purpose he recommended that workmen who were exposed to danger from flying chips should wear protective spectacles while at work. Workmen often declined to wear such spectacles—some from ignorance, and some

from vanity. He recommended that employers should be made pecuniarily liable for accidents to men in their employ, and the outcome of such a measure would be that employers would provide protective spectacles and compel the men to wear them. If the meeting could only be the means of some action being taken in that matter, it would have accomplished much good, and earned the thanks of many families.

Heating and Ventilation.—In a paper on these subjects, Dr. CHARLES A. CURTMAN, of St. Louis, alluded to the comparative advantages of the various systems of heating and ventilating public rooms, and thought the hot-air principle the best for the purpose.

The Sanitary Management of Railway Cars and Stations.—Dr. W. THORNTON PARKER, of the army, read a paper with this title. The evils attendant upon attempts to convey sick and injured persons in ordinary cars called, he thought, for immediate legislation. Every railway company should have hospital cars; and at important points, like New York, Chicago, and St. Louis, there should be a system of inspection organized. He maintained, also, that the system of railway-car privies now in use was defective, and called for a radical change.

The President's Address.—In the evening, after a reception to the members of the association, at which the Governor of Missouri made a short address, the PRESIDENT delivered an address on the *Sanitary Responsibilities of the Citizen*. He said the association had come to St. Louis in the hope of awakening in its citizens that interest in their own welfare which they had no right to disregard, if not for their own sakes at least for the sake of their children, and for the sake of the community of which they were a part. Did they realize that quite half the deaths which were happening around and among them need not happen—that their neighbors and relatives had died from diseases due to preventable causes? It was their duty as citizens as far as possible to prevent untimely deaths, and for that reason they should give every attention to sanitation. He cordially invited the citizens to attend the sessions of the association. The topics discussed, he said, could not fail to interest them, for they included the adulteration of food, the pollution of water, the general sanitary improvement of their homes, and the hygienic arrangements of public schools.

(To be continued.)

Miscellany.

THERAPEUTICAL NOTES.

The Abortive Treatment of Diphtheria.—M. Coestu (as quoted by the "Gazette hebdomadaire de médecine et de chirurgie") has employed calomel in two hundred and ninety-eight cases of diphtheria, with the idea of aborting the disease. He gives daily twenty to sixty centigrammes of the drug, divided into two doses. He reports only twelve deaths under this method of treatment.

The Influence of Baths upon the Intra-ocular Circulation.—M. Katzauroy (*ibid.*) has made some careful observations on the effect of warm baths upon the eye. He states that there is first a condition of anæmia, soon followed by marked congestion, which may become dangerous. The practical deduction is that baths should be used sparingly in acute affections of the eye.

Jequiry.—This is a dangerous drug, says Vossius ("Berliner klinischer Wochenschrift"), and ought never to be used in ophthalmic practice, since, while it does not cure either pannus or granulations, it places the cornes in extreme peril.

Antiseptics in Ophthalmology.—According to the "Gaz. hebdomadaire de médecine et de chirurgie," the use of antiseptics in ophthalmology is not only dangerous, but also unnecessary.

méd. et de chir.," Sattler has made experiments upon this subject, and gives the preference to chlorine water as an antiseptic in ophthalmic practice. Next to this solution follow corrosive sublimate, resorcin, hydroquinone, and a watery solution of salicylic acid. Boric acid and iodoform he rejects. The value of these agents is determined by their destructive action upon the micrococci found in the lachrymal sac.

Intra-venous Injections in the Treatment of Cholera.—Dr. Nicolas-Duranty, physician-in-chief to the cholera hospital at Marseilles, contributes to the "Bulletin général de thérapeutique" a paper which was thought sufficiently valuable by Brouardel to be presented at the September meeting of the *Académie de médecine*. The writer briefly describes his technique: Using the instrument of Dieulauf, he chooses a prominent vein in the neck, and passes a caoutchouc band around it above the point at which the vessel is to be opened. The fluid to be injected is placed in a graduated cylinder kept warm by immersion in hot water. The injection is made with a simple cannula in the manner of an ordinary transfusion.

After trying different solutions, he prefers the following, which Hayem has proved to exercise no harmful effect upon the blood:

Water.....	1,000 grammes.
Sodium chloride.....	5 "
Sodium hydrate.....	1 "
Sodium sulphate.....	25 "

As regards the amount to be injected, the rule is to regulate it according to the resulting phenomena. The pulse, strength of the heartbeat, amplitude of the respiration, disappearance of the cyanosis, temperature—in short, the diminution in the symptoms of collapse—all of these are valuable indications to be regarded by the operator. The author says that he has continued the transfusion for ten minutes before symptoms of amelioration appeared. Four to five hundred cubic centimetres will usually be injected at each time.

Six cases are reported at length in which the author followed out his method thoroughly. Only one patient recovered. However, they were all *in articulo* when the experiments were begun.

The writer sums up his article with the remark that, to be of any value, the injections must be given just at the beginning of the stage of collapse, when the veins have not yet lost their elasticity, and the respiration has not become superficial. At such a time the introduction of a fresh quantity of fluid into the vascular system acts as a stimulant. In any case intravenous injections should be regarded as a last resort.

The New York State Medical Association will hold its first annual meeting at the Murray Hill Hotel, New York, on Tuesday, Wednesday, and Thursday, November 18th, 19th, and 20th. The following are among the papers that are expected to be read: An Address by the President; an Address in Surgery, by Dr. E. M. Moore, of Monroe County; Transfusion, by Dr. J. C. Hutchison, of Kings County; The Duration of Contagiousness after Acute Infectious Diseases, by Dr. Alfred L. Carroll, of Richmond County; The Therapeutics of Diphtheria, by Dr. J. W. Moore, of Albany County; The Modern Progress of Materia Medica, by Dr. E. R. Squibb, of Kings County; Notes on Dislocation of the Hip, by Dr. Frederick Hyde, of Cortlandt County; Chronic Intestinal Catarrh, by Dr. J. S. Jamison, of Steuben County; Intestinal Obstruction, by Dr. Avery Segur, of Kings County; The Management of Criminal Abortion, by Dr. W. H. Robb, of Montgomery County; A Case of Acute Lead Poisoning resulting fatally, by Dr. R. H. Sabin, of Albany County; Chronic Mercurial Poisoning, by Dr. Charles Bulkley, of Monroe County; Pyæmia and Death after the Operation for Convergent Squint, by Dr. J. J. A. Burke, of Monroe County; Errors of Refraction, the Importance of their Recognition and Correction in Early Life, by Dr. H. E. Mitchell, of Rensselaer County; The Relations of Habit to Disease, by Dr. C. M. Kittredge, of Dutchess County; The Dietetic Treatment of Dyspepsia, by Dr. Austin Flint, of New York County; On Venesection in the Convulsions of Pregnant and Parturient Women, by Dr. Darwin Colvin, of Wayne County; Report of a Case of Nephro-lithotomy for Calculous Pyelitis, and of a Case of Excision of the Rectum for Cancer, by Dr. W. W. Seymour, of Rensselaer County; The Functions of the Auricles, and Double Synchronous

Amputations, by Dr. U. C. Lynde, of Erie County; An Address in Obstetrics and Gynecology, by Dr. T. Gaillard Thomas, of New York County; The Practice of Medicine Forty Years Ago, with its Comparative Position at Present, by Dr. B. L. Hovey, of Monroe County; On the Use of the Aspirator in Hydrothorax, by Dr. E. D. Ferguson, of Rensselaer County; A New Procedure in Paracentesis Thoracis, by Dr. T. F. Rochester, of Erie County; Notes on Peat as a Surgical Dressing, by Dr. W. S. Tremaine, of Erie County; Fracture of the Base of the Acetabulum, by Dr. C. C. F. Gay, of Erie County; A Case of Tubal Pregnancy, at Full Term, of Fourteen Years' Standing, by Dr. J. G. Orton, of Broome County; A Case of Tubal Pregnancy, considered in Relation to Rupture of the Tube, Diagnosis, and Treatment, by Dr. Nathan Bozeman, of New York County; A Case of Ovarian Cyst, with Operation, by Dr. T. M. Lloyd, of Kings County; Report of a Case of Dislocation of the First Phalanx of the Thumb Forward, by Dr. F. W. Putnam, of Broome County; Common Sense versus Hypothetical Medication in treating Chronic Diseases, by Dr. Jonathan Kneeland, of Oneonta County; Insanity—Preventive Measures, by Dr. John P. Gray, of Oneida County; Cerebral Epilepsy, by Dr. C. F. Macdonald, of Cayuga County; Excision of the Knee in Preference to Amputation in Certain Deformities of the Leg, by Dr. Stephen Smith, of New York County; The Relations between Tuberculous Joint Disease and General Tuberculosis, by Dr. Frederic S. Dennis, of New York County; The Curette, its Place and its Power in Uterine Therapeutics, by Dr. George T. Harrison, of New York County; Some Points in the Management of Breech Cases, by Dr. W. T. Lusk, of New York County; Women as Midwives, by Dr. T. H. Manley, of New York County; An Address on Medicinal and Non-medicinal Therapeutics, by Dr. Austin Flint, of New York County; False Albuminuria, by Dr. Gaspar Griswold, of New York County; The Early Use of the Knife in Nervus of the Cavernous-Angioma Variety as Contrasted with other Modes of Operation for Removal, by Dr. Samuel W. Smith, of New York County; Abscess of the Liver, by Dr. E. G. Janeway, of New York County; Diphtheritic Croup, by Dr. J. Lewis Smith, of New York County; Typical Cases of Diabetes Mellitus not before reported, by Dr. Austin Flint, Jr., of New York County; Report of a Case of Gunshot Wound of the Stomach—Recovery, by Dr. John H. Hinton, of New York County; Report of a Case of Ligation of the Primitive Iliac Artery for Diffuse Aneurysm of the External Iliac Artery, by Dr. J. W. S. Gouley, of New York County.

On Friday morning, the day after the meeting, Dr. Lewis A. Sayre, of New York County, will demonstrate the application of the plaster-of-Paris jacket in the treatment of spondylitis and lateral curvature of the spine, and in the afternoon there will be an excursion to the hospitals and other institutions on the islands in the East River.

The Relations of some Famous Medical Men are thus set forth by Mr. Charles Hawkins, in an interesting historical article contributed to the "Lancet": "A sister of William and John Hunter was the mother of Mathew Baillie and his gifted sister, the well-known authoress. Baillie married the daughter of the celebrated Dr. Denman, the father of the first Lord Denman, distinguished as a great lawyer. Dr. Denman married the aunt of Sir Benjamin Brodie. The second Sir B. Brodie, by his writings in science, gave evidence of his claim to be ranked as a distinguished professor of chemistry. Dr. Baillie's son, Mr. William Hunter Baillie, is one of the present trustees of the Hunterian Museum at the College of Surgeons."

The Bacillus Tuberculosis in Urine.—At a recent meeting of the Medical Society of Berlin, Herr Mendelssohn showed preparations of the *Bacillus tuberculosis* found in the urine of a patient who originally suffered from cystitis and incontinence of urine, and, shortly before death, exhibited symptoms of pulmonary phthisis. As death approached he became almost unconscious, and urine escaped in small quantities. It was thick, of a red-yellow color, very albuminous, and precipitated a thick deposit, consisting principally of pus; also a considerable quantity of whitish flakes and lumps, which were really shreds of tissue. Dry preparations were made of the sediment, and stained according to Ehrlich's method. The bacillus of Koch was found in the particles of the bladder-tissue. This preparation is especially interesting, as the arrangement of the bacilli corresponds exactly with the description Koch has given in his last work.—*Brit. Med. Jour.*

Original Communications.

CASES OF

BUCCAL TUBERCULOSIS.*

By THOMAS AMORY DE BLOIS, M. D.,

BOSTON.

CASES of tuberculosis involving the buccal cavity are certainly sufficiently rare in this country to merit mention whenever they are met with, either where it first shows itself in the mouth, or when, after manifesting its presence in other parts of the body, it finally extends itself into that region.

I do not think that we have any good reason to doubt that there is always a deposit of tubercle in the lungs before we find it either in the pharynx or in the larynx, although we may not have the physical signs in the chest to indicate its presence.

Why, then, should there be any distinction made between cases which appear primarily and those which appear secondarily in the buccal cavity?

I have the privilege of reporting to-day two cases of this rare affection, similar only in the fact that they both proved speedily fatal, which fact, indeed, is common to all the cases of this affection heretofore published. In the one, the buccal lesion was soon seen; in the other, it was the last extension of the disease.

CASE I.—J. O'C., a native of Prince Edward's Island, aged thirty years, always of delicate constitution, and inheriting from both parents a tendency to pulmonary disease. A few months prior to his arrival in Boston he exhibited signs which to his friends appeared to be sufficiently serious to warrant medical examination. To use the patient's own words, evidences of consumption were found. He did not want for good or well-directed efforts at treatment. Two months before I saw him he first noticed a difficulty in eating. The back part of his mouth appeared to him stiff and sore; the soft palate felt too thick, and this soreness, redness, and stiffness, according to his own story, gradually extended farther and farther to the front, until he came to Boston, when he very speedily found his way to the Boston Dispensary, February 8, 1883.

At the time I saw him he exhibited the following condition: The tonsils, velum, hard palate, and base of the tongue were one continuous mass of ulceration, showing that gnawed and worm-eaten appearance so often seen on the ary-epiglottic folds in cases of laryngeal tuberculosis. The edge of the velum and the uvula were denuded from this process, and farther toward the front of the mouth the mucous membrane was studded with gray nodules of tubercle which had not yet broken down. Some distance in front of the junction of the hard and soft palates there was a perforation through the bones into the posterior nares, where, with the probe, a large extent of denuded and necrosed bone could be felt on the bony septum and turbinated bones, showing that region to be fully involved in the general destructive process.

An imperfect view of the larynx was obtained with the greatest difficulty, owing to the extreme degree of pain that touching the soft palate caused, but the larynx appeared to be

free from ulceration, and, as the voice was unimpaired, except the muffling due to the thickened palate, it would seem that it had escaped the invasion of the disease. The patient said, also, that he felt no pain about the thyroid cartilage during deglutition, but that the pain at the isthmus of the fauces was more than he could bear, and he preferred not to eat at all. Certainly his appearance would have indicated that he had pretty well carried out that rule, as there was a degree of cachexia seldom seen. There was no specific history whatever, and several dermatologists carefully examined the patient with a view to discover if there was any unacknowledged taint.

Everything possible in the way of sustaining treatment was carried out, and careful cleansing and the daily use of iodoform as local treatment for the mouth; but the patient rapidly grew weaker, owing in part, certainly, to his inability to swallow solid food of any kind. A great deal of attention was paid to the treatment of the necrosed bones in the posterior nares, and what was possible was removed through the opening already mentioned, but the parts were in such a condition that nothing could be done through the naso-pharyngeal space.

This man remained as an out-patient for some weeks, deglutition becoming gradually more painful, until finally it was with the greatest difficulty that even fluids were swallowed, for even their impact against the soft palate caused the most exquisite pain. He was then sent to the Carney Hospital, from the records of which I find that:

"J. O'C., aged thirty, born in Prince Edward's Island, single, by occupation a clerk, was received under the head 'Phthisis,' March 3, 1883. He began to cough November 1st. On admission, muco-purulent expectoration, night-sweats; voice lost nine weeks ago, obliging him to close the nose to swallow. Ordered milk enema, potass. chlorate gargle. March 4th, iodoform blown into roof of mouth. March 8th, died."

An autopsy was permitted by the relatives, but, unfortunately, by some blunder at the hospital, it was not made, and this most valuable specimen was lost.

By the hospital records it would appear that no examination was made of either lungs or throat, and the voice was never lost, as stated in the record, for I saw him at the hospital the day before he died, and he spoke quite distinctly, although his voice was muffled, evidently from the perforation of the palate, but it was not at all the aphonia of laryngeal tuberculosis.

CASE II.—Miss E. D. This was more properly a case of laryngeal tuberculosis, for the first evidence of disease was derived from the throat symptoms; but, by its extension into the buccal cavity, it merits a place in this paper.

The patient, a young lady, one of the assistants at the Boston Public Library, had always enjoyed excellent health. She first noticed a hoarseness, which not disappearing under the efforts of her family physician, she saw Dr. F. I. Knight, of Boston, by whom she was examined, and who has kindly given me these few notes from his case-book:

"E. D., aged twenty-four, was examined November 4, 1882. Father died of 'lung fever,' mother died parturient, brother died, according to patient's own words, from 'consumption of the blood.' She stated that she never had had any trouble with the lungs. Had been hoarse for two months, with slight cough for eight months. Gaining flesh on cod-liver oil. Had had hæmoptysis, losing about a tablespoonful of blood. Said she felt generally well. Examination showed a superficial ulceration of both ventricular bands. Abundant moist râles in right front of chest."

After this examination she went back to the care of her former attendant. In December she came to the office of Dr. S. W. Langmaid for treatment. She was now very hoarse, and,

* Read before the American Laryngological Association, May 14, 1884.

after treatment by lime for some time, in February, 1883, by his advice, she went to Florida. Here she passed the spring months, and, although somewhat benefited by the climate, she was entirely without any intelligent local treatment. Her physician there made several unsuccessful attempts to apply nitrate-of-silver solution to her throat, causing her thereby much pain. She returned from Florida in May, and went as an out-patient to the City Hospital, where she came under my care about June 1, 1883, and from there came to my office every day. An examination of the chest was always declined, so that I am unable to state what were the physical signs at that time.

There was marked aphonia, the patient barely being able to whisper, and it was with the greatest difficulty that what she said could be distinguished at all. The pharynx at this time appeared to be normal, but the larynx in all parts seemed to be deeply ulcerated, the ary-epiglottic folds were greatly swollen and edematous, deglutition was performed with the greatest difficulty and was almost always accompanied by violent attacks of coughing, and, generally, liquid and semi-solid food had to be used. Carefully applied sprays for cleansing and local treatment were used; also occasional insufflations of morphine, and always of iodoform; also nitrate of silver and local scarification, when it appeared to be indicated. During the months of June and July there was great improvement; the voice somewhat improved, and the deglutition was much easier. Solid food could be swallowed with comfort, and there was a gain of several pounds in her weight. But during the month of August the patient again commenced to fail rapidly, and the difficulty in swallowing returned. About this time there appeared on the tonsils, particularly the right, a small, grayish spot, which closely resembled tubercle in its gross appearance. Implanting itself first on the edge of a lacuna, it seemed to progress both inward and outward, spreading into the interior and on the buccal aspect of the tonsil. The pain in swallowing seemed to be somewhat increased, but not so much as might have been expected.

All through the month of September the patient lost ground and the ulceration increased. There was considerable dyspnea, and it became evident that she could last but a few weeks longer. She was, therefore, sent to the Boston City Hospital, from the records of which the following notes are taken:

October 5th.—E. D., aged twenty-five, single. Family history fair; catamenia regular, last two months ago. Trouble began a year ago; gave up work five weeks ago; not sick abed; trouble began with cough, especially at night; dry, or with slight yellowish expectoration later, and at present thick, white, and frothy; slight hemoptysis at first; none since. Frequent chilly sensations; hoarseness for the last nine months, and loss of voice; no night-sweats; some shortness of breath; no pain in the chest; occasional palpitation of the heart; appetite good; difficulty in swallowing for the last six months, etc. Temperature 100.6°, pulse 132. Tongue slightly pale and moist. Respiration 36. Has lost forty pounds in nine months. Is weak and trembling; former weight one hundred and thirty-five pounds. *Lungs:* Dullness over both fronts, most marked on right. Under right clavicle, cracked-pot resonance. Broncho-vesicular respiration over whole right front and upper part of left. Under right clavicle, cavernous respiration. Moist râles over both fronts, most numerous on right, and bubbling râles under right clavicle. Increased whisper in both chests, but most marked on right.

Upper halves of back give corresponding signs to fronts. Urine normal, acid 1.020, trace of albumin. Sediment squamous epithelium.

Sherry, brandy, opium, carbonate of ammonium, etc.

22d.—Four days ago diarrhoea began and persisted until yesterday noon; dejections numerous, fifteen or more in twenty-

four hours; watery diarrhoea weakens patient greatly. Began to fail rapidly last night, and died at 12.45 p. m. to-day.

An autopsy was allowed, and was made by Dr. W. W. Gannett, Pathologist to the City Hospital.

E. D.—*Diagnosis:* tubercular tonsillitis; extensive tubercular ulceration of the larynx; tubercular ulceration of the mucous membranes of the bronchi and trachea; tubercular peribronchitis; bronchiectasis, and one cavity from ulceration; miliary tuberculosis of the spleen, kidney, and liver; tubercular ulcerations of the intestines.

Under the microscope, sections from the larynx showed evidence of tubercle, and many of these nodules are easily seen on the specimen.

The following note I received from Dr. Gannett:

"110 BOYLSTON STREET, April 27, 1884.

"DEAR DOCTOR: I have examined various portions of the tonsil in your case, but fail to find any evidence of tuberculosis.

"Numerous sections made so as to include parts of the wall of the cavity in the tonsil give a like negative result.

"In the tissues about the arytenoid cartilages and vocal cords, on the contrary, there are numerous tubercles.

"A diagnosis of tuberculosis or tubercular ulceration of the tonsil is, therefore, not warranted.

"Sincerely,

"W. W. GANNETT.

"To Dr. T. A. DE BLOIS."

As regards the cases of this affection on record, I regret that the "Index-Catalogue of the Library of the Surgeon-General's Office" is not sufficiently advanced to furnish me references on this subject. However, by carefully searching the "Index Medicus" from the beginning, I find cases reported in 1878 by Bordenave, Routier, Gaucher, von Ziemssen, and Laboulbène; in 1880 by Caselli and Barth; in 1881 by Zaverthal, Chassagnette, and Lennox Browne; in 1882 by E. W. Cushing and Bosworth; and in 1883 by Gungenheim, Lennox Browne, Schnitzler, and Cadier, besides the case which our friend Dr. Bosworth so kindly showed us at last year's congress. Most of these authorities cite other cases seen by other observers, so that there does not appear to be any great dearth of literature on this subject, at least in Europe.

Although Isambert says that there is little difficulty in the differentiation from syphilis, yet almost all the other authorities are very profuse in their rules for this differentiation. Routier states that one of his cases was for some time treated as syphilis, and then mistaken for epithelioma, cancer of the tongue, gummatous tumor, etc., but that the lesion healed under local applications of the tincture of iodine and the internal use of iodide of potassium, although it subsequently relapsed.

The ordinary treatment for syphilis is generally considered to do more harm than good in tuberculosis of the mouth.

The prognosis is, by all authorities, believed to be of the worst. Many cases where the local lesion has been temporarily healed are reported, but it has always relapsed when the patient has not died from exhaustion and the effects of the disease on the general health.

As Isambert states, it is at most a matter of some months.

As regards the destruction of tissue from perforation,

some of the reported cases have been examples of this, and others have seemed to stop short. Cadier reports one case of perforation of the velum with loss of the uvula.

I have had an example of this complication in a case believed to have been buccal tuberculosis, but, as I was not positive that there was not also syphilis, I have refrained from reporting it.

The record of treatment is but a reiteration of many disappointments. Lennox Browne speaks of the successful local healing of tubercular ulcerations with the galvanic cautery. Routier indorses the use of iodine and nitrate of silver. Isambert speaks of the sad consequences of their use, as it only hastens the fall of the epidermis and the uncovering of the granulations. He, like his echo, Cadier, recommends glycerin and morphine.

I have found nothing so useful and soothing as iodoform, and, although the buccal ulcerations in my cases never healed, yet their pain was always diminished, and swallowing was in one case rendered possible by its use.

I can not regard tubercular ulceration of the buccal cavity as anything else than an anomaly in the deposit of tubercle, in a case of general tuberculosis. It may precede and it may follow the discovery of the physical signs in the chest, but, so far as I have been able to find, there has never been a case in which the patient has not, sooner or later, succumbed to the ravages of tuberculosis.

DISCUSSION.

Dr. LANGMAID said, in adding a word to the history: When I first saw the girl she was so plump and finely developed that no one would have supposed she had disease of the lungs. Still, upon looking into the mouth, it was evident that there must be disease of the pulmonary organs. On examination, signs of limited phthisis were found under the right clavicle. With the patient's excellent nutritive condition, the case was one which would lead the physician to hope, with proper care, for a number of years of comparative comfort. But the laryngeal complication was against such hopes. When she came to me, dysphagia was severe, but the result of local treatment was very marked, and when she went to Florida she ate with comfort. It was hoped this relief might continue, but she had not been in Florida more than three weeks when the throat again became sore. There she could not receive proper local treatment. This is a point which has interested me in this and in other cases, namely, that laryngeal phthisis changes the prognosis regarding the general disease so much that it also necessitates a different course of treatment. I hesitate to send patients suffering from laryngeal phthisis away from home, preferring to keep them even in an injurious climate where they can receive proper local treatment to sending them away to a climate which will be better for the pulmonary condition, but where no throat supervision can be exercised. About this time a patient came to me from New Mexico, and, on examination, I found him to be suffering from an ulceration within the larynx. He had returned from Mexico because of the increasing severity of laryngeal dysphagia. I found what I believe was a tubercular ulceration in the naso-pharyngeal space, presenting very much the appearance seen in Dr. Bosworth's case shown to the society a year ago. The ulcer, however, proved not to be tubercular, and healed under treatment. But the laryngeal difficulty went on, and the man died of phthisis.

The PRESIDENT thought the paper presented by Dr. De Blois an exceedingly important one. So far as I know, he said, this

is the first case in which a post-mortem examination has been made. I do not see why the tubercular process may not be one and the same thing whether it occurs in the larynx, tongue, or pharynx, or elsewhere. Certainly the gross appearances are to my sight identical, and heretofore I have had no doubt whatever that, at least in the last stages of phthisis, there was a tubercular deposit in the special parts mentioned. Many of those present saw the girl presented last year, nineteen years of age, healthy-looking, with extensive ulceration of the soft palate, pharynx, and larynx. To look at her, no one would have supposed that she was in bad health. Still, she died within six months from exhaustion. Pain referable to the tubercular ulcer was kept entirely under control by iodoform and morphine. Furthermore, no lung complication could be detected by physical examination. It seems to me that too much importance has been attached to the impossibility of tubercular deposit occurring primarily in the upper air-passages. We may find tubercle in any other part of the body as a primary deposit, but, with reference to the tongue and larynx, some are inclined to doubt its existence. For my part, I can see no reason why the larynx may not be the primary seat of tubercle. A singular fact regarding tubercle of the upper air-passages is that the closer it occurs to the mouth or the outer world the more serious is the prognosis. Pulmonary tuberculosis may be recovered from; laryngeal tuberculosis, very rarely; while buccal tuberculosis, so far as observation goes, is never recovered from, and the symptoms are very difficult to allay.

Dr. DE BLOIS, in closing the discussion, said: Perhaps I have not brought out the fact that, at the autopsy, tubercular ulceration was found in the intestines, the kidneys, and the liver, and that there was tubercular ulceration extending well down the trachea.

THE NEW SPECIFIC FOR RHEUMATISM.

BEING AN ANALYSIS OF ONE HUNDRED AND EIGHTEEN CASES TREATED WITH THE OIL OF GAULTHERIA.*

By H. H. SEELYE, A. M., M. D., AMHERST, MASS.,
LATE HOUSE PHYSICIAN IN BELLEVUE HOSPITAL.

THE contribution which I have to present to the members of this society to-day embodies the results of an eighteen months' personal experience with the oil of gaultheria in the treatment of the various types of rheumatism, the observations having been made in three of the wards of a large hospital where special advantages were offered for testing the merits of the drug.

About two years ago I believe the oil of wintergreen was first suggested as a substitute for salicylic acid and its salts, the latter being a chemical derivative from the former. Very soon after this our visiting physician at the hospital, Dr. Henry F. Walker, of New York, proposed that we experiment for a while with this new remedy to see if it had any merits. We accordingly began to use it at once, and with such surprising results that from that day onward it was always our main reliance in the treatment of all rheumatoid affections.

The medicine we found could be administered in various ways, the most agreeable being in capsules, either alone or mixed with salicylate of sodium, or in soda-water as a flavoring. But the method we employed the most was to give it

* Read before the Hampshire County, Mass., Medical Society, July 9, 1884.

in an emulsion of ten minims of the oil to half a drachm each of glycerin and water. If the patient had been sick for some time, and the inflammation of the joints was extensive, we usually ordered two drachms of this mixture every two hours during the day, and every three hours throughout the night. Under this treatment almost invariably within twelve hours the patient would express great relief, and by the end of twenty-four hours the pain and swelling would have left all the joints except, perhaps, a little in some one articulation; and there would only remain a slight stiffness of the previously inflamed parts, due probably to the distension of the adjacent tissues by reason of the swelling, which had now disappeared. Before or about this time, however, the patient would generally complain of some ringing in the ears and deafness, similar to that produced by large doses of quinine, but usually not so markedly annoying in character, and he would be apt to have some headache or a sensation of fullness in the head. These symptoms occurring synchronously with the cessation of pain, tenderness, and swelling from the joints, and with a sudden fall of temperature to the normal, were generally considered an indication for diminishing the dose of the medicine, and it was therefore usually reduced to one drachm every three or four hours, according to the relative amount of the cerebral and joint disturbance. If too much of the medicine was still given, its evil effects became more marked. The patient would now experience a loathing of the drug; nausea and vomiting would set in; the deafness, tinnitus aurium, and headache would increase; the muscles of the hands, limbs, and face would become tremulous; the countenance would be flushed and the whole body be bathed in a profuse perspiration; and at length the patient would become delirious, till in some instances the symptoms so closely resembled those of delirium tremens that it was often difficult or quite impossible to tell whether they were really the manifestations of the physiological limits of the remedy, or those of an alcoholic patient deprived of his accustomed stimulants. These extreme symptoms, more or less modified, were observed by us in perhaps eight or ten cases of acute articular rheumatism, but they almost invariably occurred in patients who had been hard drinkers, and in whom the attack of rheumatism was most probably due to some unusual exposure to cold or wet while in a state of intoxication. In the large majority of cases only a little ringing in the ears was complained of, and this would soon cease upon the diminution or complete withdrawal of the drug. There were also very many cases in which no evil results were ever manifested, but the patient speedily recovered without experiencing any annoyance.

There would always be a certain number of cases which would yield promptly to the remedy, so far as relieving the acute suffering, reducing the inflammatory swelling, and lowering the temperature were concerned, but still a little pain on motion, or a slight stiffness, would hang about some one joint, usually the shoulder, wrist, finger, or ankle, and it would be several days longer before the patient could say that he was perfectly free from pain and felt well. Again, there would be comparatively few patients who, after being speedily

relieved, would be up and moving about the ward for some days without taking any of the medicine, and then there would come a sudden relapse, and the pains would return, though with less severity, in one or more joints. But here a renewal of the remedy usually induced a rapid recovery. In order to guard against such relapses and to be sure that the cure was permanent, it was our custom to keep the patient in bed and to continue the medicine in smaller and less frequent doses for at least two days after all symptoms of the disease had disappeared, then to retain him in the ward for two or three days longer without giving him any medicine but tonics, and then, if there was no return of the symptoms, to discharge him cured. In a very large majority of cases the patients themselves asked, about this time, to be discharged, because they felt so perfectly well.

The history of a German patient, thirty-five years of age, who was admitted to the hospital last spring, is a good illustration of how much more rapid are the cures wrought by this medicine than by those used years ago. This man had, in the past fourteen years, had two attacks of rheumatism, one of which confined him to the house for fourteen weeks, and the other for twelve weeks. Four days before admission he was taken with his third attack, which, beginning with pains in his legs, shifted about until it involved both ankles and knees and the right hip joint, so that he was quite unable to walk. These joints were tender and swollen, he had a temperature of 102° , and a systolic cardiac murmur could be heard both at the apex and at the base. He was ordered to take ten minims of the oil of gaultheria every two hours. Twelve hours later he expressed himself as free from pain, and there was afterward no recurrence of his symptoms. Five days later he was discharged, at his own request, cured. His shortest previous attack had lasted twelve weeks, while here he was effectually cured in twelve hours! His astonishment at his speedy relief was as great as it was gratifying to us.

The one variety of rheumatism in which this remedy was found to be most efficient and rapid as well as permanent in its action, is what is commonly known as acute articular rheumatism, and the more acute the attack, the more joints are involved, the more inflamed and swollen they are, and the higher the temperature, so much the more speedy and complete is the cure apt to be. It is, in fact, in these worst of all cases that the remedial power of this drug is most wonderful to see. Yet it must not be supposed that it is of insignificant value in the more subacute forms of the disease; for here too it almost invariably diminishes the severity of the suffering, and, after a time, often effects a radical cure.

In the chronic forms of rheumatism the action of the remedy seems to be limited in most cases to merely giving prompt relief from the acute pains and swellings attending exacerbations of the malady, and for this purpose it is very efficient. But, like most other drugs, it is powerless to correct the permanent damage done to joints which have long been undergoing morbid changes in their fibrous and cartilaginous structures. The same statement is true, as a rule, in regard to those other obstinate forms of the disease

known by the various names of gouty rheumatism, arthritis deformans, rheumatoid arthritis, gonorrhœal and syphilitic rheumatism, etc. In the active stage of all these some temporary relief will usually be afforded, while a complete recovery under its influence is very rare.

Muscular rheumatism, lumbago, coxalgia, sciatica, and the like seem to be variously influenced. Some patients, after the medicine is begun, experience almost immediate relief, while others do not seem to be benefited at all. Possibly this uncertainty of action is dependent upon whether the muscular and neurotic pains are primarily due to an irritation from some morbid element diffused throughout the circulation, which the medicine, it may be, counteracts, or whether they are due to a simple inflammation of the fibrous coverings, from some strain, bruise, unusual exposure, or overaction of the affected part.

As regards the frequency of cardiac complications developing under this plan of treatment, it is certain that the liability to them is not increased. In one or two of our cases a pericardial or endocardial murmur seemed to develop while the patient was under observation, but in more instances a murmur which was audible upon admission disappeared entirely under this treatment. It is doubtful if the medicine has any such depressing action on the heart as is attributed to salicylic acid and its salts. There was, however, one death among the cases recorded, which occurred so suddenly and unexpectedly as to raise strong suspicions at the time as to how much the medicine had to do with it. The man had for several days previous to his admission to the ward been under treatment for acute alcoholism, from which he had about recovered, but he was now suffering from arthritic pains, probably brought on by recent exposure. He was put on the rheumatic mixture, which speedily gave him relief. Thirty-six hours later, at midnight, he was asleep and apparently in excellent condition, having a strong, regular pulse. No cardiac murmur had been made out. One hour later he was found dead in bed, where he had seemingly expired suddenly from heart failure. He had not taken any of the medicine for several hours previous. Whether this death was due to fatty degeneration of the heart in a persistent consumer of alcohol, or to an unrecognized valvular lesion, or to the depressing action of the medicine, or of the rheumatic poison circulating in the blood, could not be determined, as no autopsy was allowed. But this sudden collapse was probably a coincidence with, or a consequence of, the disease itself, rather than a result of the treatment pursued.

Having now presented, in a general way, a few facts brought out in the course of our experimentations with this new anti-rheumatic remedy, its advantages over all previous methods of treatment will be shown more vividly by presenting a few of our statistics in a tabulated form. Though "figures can not lie," yet they can often come short of expressing the whole truth; and so those about to be presented will represent only the relative rather than the actual superiority of this new method of treatment. These figures are all taken from the records in the history-books of the hospital, and they include every case of rheumatism in any form treated by the oil of gaultheria, and that includes

every case admitted to any one of the two male and one female wards in which this remedy was being tested. Of course, many of these cases of rheumatism had at the same time associated complications, such as heart, pulmonary, cerebral, or nervous lesions, necessitating the use, to a greater or less extent, of certain other drugs or remedies indicated by these. Then, too, in some obstinate cases, where only tardy or partial relief was given by the gaultheria, other older and well-established remedies, such as blisters, iodide of potash, and the alkalies, were brought into requisition as adjuvants to the drug on which the main reliance was placed. Still, in the majority of uncomplicated cases, recourse was had to only the one kind of medicine until all the symptoms had disappeared, and it was only after convalescence had become fully established that iron or other tonics were added, in order to hasten the repair of the system, now more or less broken down by the previously vitiated condition of the blood. It is altogether probable that none of these adjuvants had any material influence in shortening the duration of the acute inflammations; while iodide of potash, colchicum, and tonics possibly did much to relieve, without curing, some of the cases classed as chronic, gouty, rheumatoid, and the like, and which have, therefore, not been tabulated as to their duration with the regular acute cases, which were generally cured by a more limited course of medication. These chronic cases were seldom if ever cured, but in most of them there was marked benefit derived from the treatment, the gaultheria seeming to do most good in relieving the most aggravated symptoms. Any case that was completely cured within six weeks was considered as acute, and few, if any, that resisted treatment for that length of time, ever yielded entirely. All such have, therefore, been classed and tabulated as chronic, gouty, rheumatoid, muscular, gonorrhœal, syphilitic, neurotic, and so forth, according to their apparent cause.

Of the class termed acute, there were ninety cases which came under this special course of treatment within the eighteen months of experimentation, and of the chronic and other varieties there were twenty-eight recorded cases—making a total of one hundred and eighteen cases treated in the three wards under observation. A few other acute cases, treated similarly in other wards of the hospital and in private practice, bore out the same deductions as were drawn from these recorded cases.

In all of the tabulated cases care was taken not to use salicylic acid in any form, lest it might influence and vitiate the result, and, moreover, it was desirable to compare the effects of this new treatment with those of the salicylate method, which was still the main reliance in most of the other medical wards of the hospital. It was therefore the task of the writer to collect an equal number of successive cases treated, as far as possible during the same months, by the salicylates, in other wards, and in the same three wards during the months prior to the beginning of the gaultheria plan of treatment, and then to tabulate and compare the results of these two methods. Recognizing fully the valuelessness of statistics, unless honestly and conscientiously compiled, he observed every precaution against being influenced by prejudice, and every acute case was taken and

tabulated in the exact order in which it was recorded in the various history-books consulted, and wherever there was any doubt as to the justice of the record the benefit of it was given to the other side. So it is his firm and honest belief that the figures about to be presented do not overestimate the relative superiority of the one over the other method of treatment.

It must be added, however, that in looking over the history-books of the different wards, it was found in many cases that the purely salicylate treatment had not been exclusively carried out, but had either been supported or soon entirely supplanted by other remedies, including the alkalies, iodide of potash, colchicum, iron, quinine, cod-liver oil, and local applications; yet in all these cases the salicylic acid was probably the chief reliance and the most efficient agent in the ultimate cure.

(To be concluded.)

THE INFLUENCE EXERTED ON THE SINGING VOICE BY GLANDULAR HYPERTROPHY AT THE BASE OF THE TONGUE.

By HOLBROOK CURTIS, M.D.,

LARYNGOLOGIST TO THE DEMILT DISPENSARY.

THE fact that glandular hypertrophy—analogueous to the adenoid growths found so frequently invading the pharyngeal vault—may appear at the base of the tongue, and enter as an important factor into the diagnosis of diseases of the throat, seems to have been entirely overlooked by laryngologists. In no text-book treating of throat diseases can I find mention made of the fact that the condition may exist, nor have the authors who are considered to be authorities on the mechanism of singing alluded to this pathological condition, which, either by direct mechanical obstruction or by reflex influence, may be the immediate or remote cause of *dysphonia*. The subject has lately been presented to me in such interesting form that I do not hesitate to give the results of my experience and research to the profession—a thing most conveniently and concisely done by citing from my note-book several illustrative cases:

CASE I.—Miss Rose B., aged twenty-four, presented herself to me eighteen months since with the following history: The patient was brought up in a small town in California; was possessed of a remarkable voice, which led to an engagement as soprano in one of the larger churches of San Francisco. Here she attracted so much attention that a well-known impresario induced her to join his company, to take the part of a prima donna, who, though advertised, had been suddenly taken sick. After ten days of constant study and rehearsal she sang brilliantly the leading rôle in "Martha." At the close of the San Francisco engagement she traveled with the company to Denver, Col., where she contracted an *acute laryngitis*. Though unable to speak above a whisper, she continued to sing for six nights in "grand opera," with constant rehearsal, at the end of which time her voice left her entirely. The patient took a complete rest, and put herself under medical treatment; but, though the cords showed no apparent change, and nothing seemed to be the matter with her larynx, she never regained her voice to such an extent that she was enabled to resume her singing for any considerable length of time. When she placed herself under my treatment she had been in the chorus of a bur-

lesque opera company of this city for the space of two years. She complained that her voice would be brilliant for a night, but that the next evening she was often unable to sing at all, flatted continually, and broke on anything above her usual middle register. Her voice became tired after speaking or singing, and she often lost it entirely. She had been told that she had paralysis of the cords, had been treated with sprays, electricity, and constitutionally, but never seemed to improve. Continued rest only gave her a few days' improvement. A careful examination of the *larynx* revealed nothing abnormal; but a view of the vocal cords was extremely difficult, owing to an apparently relaxed condition of the epiglottis. Only with a high-pitched (E) sound could I see the cords in any of their extent. By gentle traction on the tongue I saw in the mirror a luxuriant glandular enlargement at the base of the tongue, crowding into the *glossopiglottic fossa* to such an extent that the epiglottis was prevented from assuming its vertical aspect, hence accounting for the difficulty I had experienced in viewing the vocal cords. The epiglottis itself was congested, but the larynx as well as the pharynx was anæmic. With the exception of this condition, there was nothing to note. The patient was in excellent physical condition, and could not account for the throat having "rusted out." I immediately instituted a tonic treatment, combined with small doses of iodide of potash, and every few days made applications of chromic acid to the glandular hypertrophy. All exercise of the voice was denied, and every attention was paid to general hygiene, much out-door exercise being advocated. After the growths had been effectually removed, I simply made astringent applications to the throat at intervals, and she commenced a limited use of the voice. She informed me that the "tired feeling" in her throat, and the pains which often "shot up to her ears" when she had used her throat too severely, had never recurred since the hypertrophy had been removed. At the end of six months Miss B. was again assuming principal rôles, and she lately writes me that her voice has been steadily improving ever since.

CASE II.—Mr. G., baritone, of an opera company, came to me in October a year ago. His voice was uncertain: always "tired out" when even but slightly used. He had lost engagements on account of his uncertain register, had dropped from "principal" to "chorus." He was worse after stimulating. He had dull pains in the throat, and always felt like clapping the throat with his hand and swallowing. He had consulted several eminent specialists of this city and in Boston, and obtained but temporary relief. Examination revealed a condition similar to that cited (Case I) above, with the exception that an infiltration process had invaded the diseased follicles, so that hard, cheesy nodules were readily removed by the aid of curved forceps. The hypertrophied follicles impinged on the epiglottis in the same manner as mentioned previously. I treated the case temporarily with a solution of equal parts of liq. ferri subsulphatis, tr. iodinii, and glycerin, which relieved him and allowed of his continuing his engagement. However, on the first vacation he took advantage of I made applications of Vienna paste, after forcibly drawing his tongue forward—a treatment more painful, but attended with quicker results, than that with chromic acid. Following up the removal of the glandular tissue with a course of astringent treatment, I had the pleasure of discharging my patient in March comparatively well.

CASE III.—Miss S., aged nineteen, came to me in May last. She said she had lost her voice suddenly in January "after singing with a severe cold." She had rapidly lost flesh. The condition had been diagnosticated as *laryngeal phthisis*. She complained of severe pains in the throat, shooting down to the clavicle and up to the ears. She had not spoken aloud for three months, communicating entirely by means of a writing-

pad which she carried. She could speak a few words aloud, but the effort was invariably followed by such severe pain in her throat that she seldom made the attempt. There was no cough, except a nervous hacking, caused by a tickling sensation and feeling of great dryness when she tried to speak. When she appeared at my office her neck was covered with scars, the result of frequent applications of fly blisters externally, cantharidal collodion, etc., used to set up counter-irritation. There was marked sensitiveness on perussing over the superior laryngeal region. Laryngoscopic examination showed the vocal cords to be normal, and there was no pathological condition in the *larynx* or the *pharynx*, except excessive anæmia, but at the base of the tongue there was an hypertrophied mass of tissue, soft in consistence, presenting the general appearance of such a mass of agglutinated adenoid vegetations as one sometimes sees in the pharyngeal vault. The hypertrophic tissue was of the size of a walnut, and had adapted itself in conformity with the outlines of the epiglottis, forming a soft cushion anteriorly. From fragments which I was enabled to examine microscopically, I was led to believe the growth to be adeno-myxomatous, loose in structure, and to have undergone no fatty or caseous degeneration.

Profiting by past experience, I at once employed Jarvis's snare, together with caustics, and, to my surprise, at the end of ten days she could speak for some minutes without pain. In three weeks' time, the growth having been entirely removed, she returned to her home in the country. I directed that applications of iron, iodine, and glycerin should be made every other day, and taught a member of her family how to use the brush by the aid of a No. 8 mirror. I am informed that to-day the patient is perfectly well.

A consideration of these cases will, I think, serve to call attention to the fact that hypertrophy at the base of the tongue, and in many cases very slight hypertrophy, easily overlooked in laryngoscopic examination, will account for voice failure, either by direct mechanical obstruction to the free opening of the epiglottis, or by a reflex action exerted on the motor laryngeal nerves.

29 WEST THIRTIETH STREET.

ON THE PREVENTION AND TREATMENT OF PUERPERAL FEVER

FROM AN ETIOLOGICAL STANDPOINT.

By W. D. SCHUYLER, M. D.

(Concluded from page 407.)

Treatment of Puerperal Fever and of Puerperal Septicæmia.—For the treatment of these affections, when such are set up—as they comprise similar pathological ensembles—the means to be resorted to are, therefore, in the main, the same. In septicæmia, however, there is likely to be present a greater degree of adynamia, which especially indicates, on the one hand, tonics, on the other an avoidance of all medication which depresses vital action.

However the views herein advanced may differ from those advocated in Dr. Thomas's paper as to the character and ætiology of these diseases, and, therefore, as to the *rational* indications to be followed for their prevention, yet in respect to an improved therapeutics to be adopted in their treatment, and especially in regard to the main measure so prominently brought forward by that author—the use of antiseptic injections into the vagina, or into the uterine

cavity when such are indicated—I am in entire accord with him. Such injections for the purpose of removing septic materials, of destroying the local action of a contagium (zymotic), or of checking an absorbent action (septic) in and from the generative tract, are in accordance with a most natural indication, and, happily, are very efficient in their results.

No physician—who has pursued, almost hopelessly, for several days and nights until death has terminated the scene, the methods of treatment advised and practiced prior to antiseptic washings—can fail to be thankful to Dr. Thomas for his paper, and especially for his prominent introduction of this measure.

That intra-uterine injections have not been more used heretofore, in view of the danger apprehended from the passage of the fluid through the Fallopian tubes and into the peritoneal cavity, is most natural. Now, however, with greater experience, and upon rational grounds, we know that, on account of the inflammatory endometrial swelling which has occurred and is present, those tubes are closed, and that we may boldly resort to the measure when proper indications for its use exist, especially if we operate with suitable apparatus and with due caution.

The indications to be followed in the treatment of both puerperal fever and puerperal septicæmia arise from local and general conditions, and are both causal and symptomatic.

The local or causal are to empty, cleanse, and disinfect the generative tract, wherever such may be the seat of infection, of or zymotic or septic action. This is accomplished by resorting to the measure referred to, disinfecting or aseptic injections, which injections evacuate putrid material and destroy putrescent or poisonous zymotic action.

The special indication for injections—which I hold should lead all other measures of treatment—and, equally, for repeating the operation, is a sudden and otherwise unexplainable marked rise of the temperature. Whenever there occurs such a thermal rise in a puerpera, especially if there is reason for believing the woman has been exposed to the contagium of puerperal fever, or for thinking she has retained placenta, or retained decomposing clots, or if any other reason exists for suspecting that septic or zymotic action is going on; and, if with this thermal rise there are an accelerated pulse, cessation of lochial discharge, irritability or paresis of the bladder, abdominal tenderness and tympanites, the question of exploring the canal and of giving an aseptic injection becomes paramount to all others; and, in general, a temperature marking of 105° or upward will decide in favor of the operation. If the indication is correct and well met, a reduction of from 1° to 2½° may be caused, with other general and local relief.

For a repetition of injections the thermal state should mainly be relied on; but, in the early stage of the process, this should also depend on the character of the washings or returning fluid. If the returning water is offensive or contains much *débris*, this fact should indicate their further necessity, and their periodical repetition until the generative tract is thoroughly cleansed and the septic or zymotic action is controlled.

Usually two or three injections daily will suffice. But where the temperature, especially the local temperature, does not fall satisfactorily, they may be repeated oftener.

The special antiseptic to be employed must be determined by the operator. I have employed, with satisfactory results, liquor sodæ chlorinatæ, largely diluted; bichloride of mercury; and also carbolic acid. The corrosive chloride of mercury, 1 to 1,000 or 1 to 2,000, is most preferred.

The injection should be abundant and at a temperature of about 100°, more or less.

For an injecting-tube I prefer a soft, smooth rubber catheter, a No. 10 or 12 (American scale), to either the Chamberlain or Lyman injecting-tubes. The soft catheter is to be preferred for its convenience, flexibility, smooth surface, and small size. The glass tubes are objectionable, because they are inflexible, and are liable, therefore, to cause unnecessary pressure or wounding; they are also unnecessarily and inconveniently large. Their great size also may render them difficult of introduction into the uterine cervix, or, if readily introduced, they may so fill the canal as to obstruct a return flow of the injected water, and particularly of bits of placenta or of placental membranes, which would otherwise be evacuated by the outflow. Being large, they require a great deal of water to fill them, which volume is less readily controlled than a smaller stream, and, therefore, may do more harm. The eye of the soft catheter being near the end and yet not in the end, it carries the stream to the uterine fundus without allowing it to impinge directly against it, and hence is not so likely to dislodge plugs from the open-mouthed vessels and cause injurious hæmorrhage.

The soft catheter is more easily cleansed and more conveniently carried about, and, lastly, is more readily introduced in the various positions a woman may be compelled to lie in. The syringe I prefer is the Davidson's. It is more convenient, and does not, like the fountain-syringe, require to be taken down to be refilled; and with it the force of the stream may be carefully graduated.

Preparatory to giving an injection, instead of bringing the woman's buttocks to the edge of the bed, the legs outside, the feet resting on chairs, I put her in Sims's position, the hips being elevated on pillows or folded blankets. This is not a difficult position to place the woman in, it does not expose her, and it admits of a ready outflow of the injected water over the thigh, which may be caught in any shallow receptacle. Having placed her in position, I introduce a speculum—a Sims's may be used if one is at hand (I use my own, a modified Sims's, which distends the vagina in four directions, is self-retaining, convenient, and affords a clear inspection of the canal and cervix)—and then, carrying the catheter as high as I desire, or see indications for, I throw in the injection with such force and for such time as the requirements demand. In this manner, illuminating the parts by reflected light with a laryngeal head-mirror, I not only see what I am doing, and the results of the washing, but I am also thereby better able to graduate the force of the stream by the effects produced. Again, by directly observing the washings, I can tell whether shreds of membrane or bits of placenta are being discharged, whether the

soiling of the washings comes from the uterus or from the vagina, and, lastly, the effect of the syringing upon local inflammatory, diphtheritic, or catarrhal conditions. The question of *admitting air* to the vagina by speculum distension, where antiseptic injections are being used, need not occupy us; no harm can result from it.

As to whether the administration of injections should be intrusted to the nurse, I should say no. A matter of so much importance can not be too carefully watched, and the necessary attention can be expected only of a responsible operator. The danger to be apprehended from causing peritonitis by intra-uterine injections of hot water when an inflammatory action is present within the womb is very slight; and if a soft catheter is used in lieu of a glass injecting-tube, and there is an opportunity afforded for the free return of the water, it may not be accounted of sufficient importance to delay the operation on that account. If, however, there is no endometrial congestive or inflammatory action, causing swelling, present (which may readily be determined by placing the thermometer within the womb), and the organ is in a lax, dilated state, then the case is altered, and injections should be administered with caution; and, when given, should contain liq. ferri persulph., or, better, tincture of iodine, which may be added to the antiseptic solution, especially if the antiseptic used is the mercuric bichloride.

Believing that the sheet-anchor of successful treatment of the puerperal, septic, or inflammatory febrile maladies lies in *properly made injections*—either vaginal or uterine, as indicated—I feel that I can not too strenuously insist upon an adoption of the manner herein set forth of giving them.

External applications, covering the abdomen, of a stimulating or sedative character, as the condition of the patient may indicate, besides imparting an agreeable warmth and promoting nutritive changes, act derivatively, and are valuable adjuncts to the intra-uterine or vaginal treatment. There is another general indication of a curative nature of value which may not be unheeded. This is to stimulate lymphatic, alterative, and excretory action, and it is fulfilled by the administration of small but frequent doses of bichloride of mercury and of iodide of potash. From the administration of the latter especially—given in one-third-of-a-grain doses, largely diluted in water, every hour—I have seen good results.

The *symptomatic indications* are to relieve pain, control fever, and sustain the strength.

For the relief of pain, morphine, given hypodermically, acts with certainty, and this is the most convenient as well as the safest method of administering that potent drug. Given by the mouth, in all maladies where digestion is sluggish—as it is likely to be in puerperal fever—morphine does not always effect prompt results, and may, from repeated doses, accumulate, and thus lead to a dangerous narcosis—which danger is all the more to be apprehended where there is present the depressed vital action which forms an early prominent feature of the puerperal febrile maladies.

But there is a further question in regard to the exhibition of opium (or its alkaloids) in puerperal fever, outside

of what constitutes the proper manner of giving it, which has to do with the soundness of the indication for its early and prominent use as a curative remedy.

From the beneficial effects of administering opium in traumatic peritonitis—evidently due to the rest afforded the affected part by its inhibitory action upon intestinal peristalsis and upon deranged nutritive processes which lead to the development of intestinal gases, as well as to its more certain anodyne action—and from its effects in idiopathic peritonitis—evidently the result of its diffusible action, in addition to those effects above noted—that drug has made such a reputation as a remedy in the peritoneal maladies that it has come to be regarded as *quite specific*, and, as such, it has been exhibited in puerperal fever.

That it has no *specific curative action* in puerperal peritoneal fever is evident from many trials, and quite as many failures, in the past, in the lying-in wards of Bellevue Hospital.

During my service in that institution in 1870 and 1871, and while in charge of the obstetric service, there were many cases of puerperal fever treated upon the *opium plan*, which was then in vogue—several of them by myself and assistants—in which morphine was administered in accordance with indications derived from the temperature, the pulse, and especially the frequency of the respirations (the latter being reduced to a semi-narcotic frequency, from observations made every two hours or oftener, day and night), and always with the same result—*death of the patient from exhaustion* in a varying number of days.

This experience—one of many in the above-named institution—clearly, to my mind, disproves any claim which may have attached to the drug as a specific in such cases.

It has already been alluded to that the action of morphine upon the nutritive functions, where an opium habit has not been established—in doses sufficiently large and frequent to affect reduction of the pulse and respirations—is inhibitory.

To the extent that it produces vital inhibitory action in puerperal peritonitis, a malady which rapidly promotes exhaustion, its use is grievously detrimental. Besides, when the treatment is pushed to the extent formerly, and possibly now, advised—of bringing the respirations down to fifteen, twelve, and, as practiced in some cases, to six, or even less, in a minute—the profound effect produced is most dangerous, as it exactly simulates extreme exhaustion, from which it can not be readily differentiated, on account of which it therefore may be unconsciously carried to a dangerous if not fatal narcotism. Again, as the effects of the drug add to the depression of exhaustion, it not infrequently promotes a dangerous result, which otherwise might not have occurred, or would not have occurred so early. From which facts, and upon general grounds, I believe morphine should be resorted to with hesitation, and its use closely watched.

It is held, however, that there is a tolerance of morphine in peritonitis, and that, therefore, large doses may be administered with safety. This tolerance can not be shown to be specific; but it is probably due to the general tolerance well recognized in all pathological states resulting from pain.

Hence, although of value as a means of allaying pain directly and of checking vermicular action of the intestines and its results, and of some benefit by its diffusible action, yet the detriment morphine works by depressing the vital functions, and the no inconsiderable danger attending its use from its liability to occasion fatal narcotism—*euthanasia*—constitute limiting indications for its employment.

I hold, therefore, that it should be administered with great care, and *only* where it is demanded by *otherwise uncontrollable pain*.

I have been led, in what has been said, to define a rational use of morphine in the treatment of the puerperal maladies: 1, because of the extent to which (advisedly) the opium treatment is resorted to in those maladies; 2, because of the greater dangers which attend such (authorized) treatment when it is not discreetly limited, especially in the depraved utero-peritoneal affections; and 3, at this time, because of the prominence given to morphine injections (hypodermic) by Dr. Thomas, who, in his paragraph 1, under Treatment, thus alludes to it: "1. As soon as a diagnosis of septicæmia (puerperal fever) is determined upon, all pain, nervous perturbation, shock, and mental anxiety, should be greeted by the hypodermic administration of ten minims of Magendie's solution of morphine, unless some special and very decided idiosyncrasy with reference to opium be ascertained to exist; and throughout the severity of the attack, when suffering of mind or body occurs (perhaps this will be about once in every six or eight hours), this should be repeated."

For reasons set forth, I would counsel that a resort to this drug should be from a secondary, rather than from a primary, consideration. I hold that the first thing to do, when the occurrence of either puerperal fever or puerperal septicæmia is suspected, from the general symptoms or from the history of a probable cause, is to clearly make out the diagnosis—both as to the site of the infecting lesion and as to its character. While these points can be presumably determined by the history, yet they should be verified by ocular, specular examination, as set forth, which should at once be made. The proper removal of a septic infecting mass, or the aseptic treatment of a contagious, inflammatory, zymotic action, should at the same time be effected. And if, after such local removal or treatment, pain is present and continues, and, furthermore, if such pain continues after external cataplasms have been applied or soothing applications have been made, and also after a diffusible medication—which is a physiological, rational method of relieving pain—has been tried, then a resort to morphine is justifiable, and its subsequent administration should only be *pro re nata*, as a *dernier ressort*.

In some cases an efficiently conducted local treatment will obviate the necessity for morphine throughout. In my experience, the occurrence of "nervous prostration, shock, and mental anxiety" is not constant in either puerperal fever or puerperal septicæmia; but, if those symptoms should be manifested, they do not in themselves indicate morphine rather than some other sedative or tonic drug. The further treatment consists in meeting the febrile indications and supporting the strength of the patient. Febrifuge medi-

cines should be such as also promote lymphatic action and secretion from the kidneys. Frequent sponging with tepid water containing a slight amount of soda, followed by inunctions of oil, cools the surface, stimulates the skin, and both refreshes and supports the patient. Antiseptic poultices—spongio-pilin may be substituted for the cataplasim—worn upon the abdomen, act beneficially. I have had no experience with the cold coil—not believing the action of prolonged cold beneficial in febrile conditions except where such are due to local traumatism—and therefore can not speak further upon that point. Quinine, as a tonic in small doses, acts beneficially. Much good results from a carefully administered diet, which, I believe, is best made up of beef-tea, milk—which is often not digestible unless peptonized, especially after any considerable febrile action has been present—animal broths, gruel made with milk and water, and cod-liver-oil emulsionized by thorough trituration with pancreatin or some other ferment. The stomach, however, should not be overloaded, and a scanty, well-chosen quantity will often afford more sustenance than a larger amount not readily digested. It should not be forgotten that the gastric function is profoundly affected in these maladies from pressure, from contiguity of morbid action, and from the depression of the sympathetic nervous function; and the question of food should be managed accordingly.

Attention to the bladder should not be omitted, and, where the catheter is required, the soft, male rubber instrument will be found more convenient than the female catheter made of silver. The soft catheter is as readily introduced, and with it the water can be discharged into a receptacle at the side of the woman, which gives her less annoyance and trouble than where such receptacle must be placed between and under the thighs.

A DISPENSARY DRESSING FOR ULCERS OF THE LEG.

By F. BARQUHAR CURTIS, M.D.

At the Out-patient Department of the Chambers Street Hospital we have lately found a very convenient dressing for ulcers of the leg in Lister's boric-acid dressing applied with a crinoline bandage. Its advantages are: (1) firm and lasting support, even enabling patients to work; (2) asepis, and non-disturbance of the part; (3) economy of time to both surgeon and patient; (4) economy of material, one dressing costing but little more than any ordinary dressing and bandage, and lasting three times as long.

The mode of application is as follows: The leg and foot are thoroughly washed with a 1-to-40 carbolic-acid (or 1-to-1,000 corrosive-sublimate) solution, and the ulcer itself is washed with a saturated solution of boric acid. Over the ulcer is put a piece of thin gutta-percha tissue (as a substitute for the Lister macintosh), large enough to extend about one fourth of an inch beyond its edges on all sides, which has been soaking for some minutes in the boric-acid solution. The leg is wiped dry, sufficient borated or salicylated cotton to take up the discharge is laid over the ulcer, and the rest of the leg from the ankle to the knee is wrapped

in a half-inch layer of cotton batting. An ordinary bandage is applied to the foot.

The crinoline bandage (three inches wide, ten to twelve yards long) has meanwhile been soaking for five minutes in water, and it is now squeezed quite dry and snugly applied over the cotton from the ankle to the knee, making a thickness of three or four layers. Care must be taken to have the cotton project beyond both its upper and lower edges, as they may excoriate the skin when dry and stiff. In half an hour the crinoline will be dry; but, if time is important, an ordinary bandage may be applied outside of the crinoline, and the patient dismissed at once.

We direct our patients to return in a week; but to come at once if they should have any pain, or if the discharge from the ulcer should come through the dressing. But the dressing can be worn for much longer than a week, as shown by the following cases:

CASE I.—Timothy F., aged forty years, laborer.

February 8th.—Four or five months ago patient received an injury to his leg, causing an ulcer, which was healed, but has returned. He is in fair general condition. On the anterior surface of the middle third of the left leg is a circular ulcer $2\frac{1}{2}$ inches in diameter. The base is dark red, granulating, level with the surface of the skin; the edges are flat, but without cicatricial action; the discharge is abundant and purulent.

Apply the boric dressing described above with an ordinary bandage.

26th.—Ulcer now $2 \times 1\frac{1}{4}$ inch. Base paler, discharge less, edges cicatrizing. Has been dressed several times. Redress, but with the crinoline bandage as described above.

March 5th, 12th, and 19th.—Redressed.

April 3d.—Dressing untouched for fifteen days. Ulcer now 1 inch in diameter. No sign of irritation of surrounding skin. Redress.

25th.—Redressed on 16th. Now ulcer is entirely healed.

CASE II.—James McC., aged thirty-five years, deck hand.

March 26th.—Two weeks ago patient received a blow on the shin. Now on anterior surface of leg, above the middle, is a black slough 2×1 inch, firmly adherent. His general condition is good. Apply 1-to-40 carbolic-acid compresses until slough separates.

April 3d.—Slough has fallen, leaving an oval, concave, 2×1 inch ulcer. Apply regular boric-acid and crinoline dressing.

11th and 22d.—Redressed.

March 27th.—Dressing has been worn for thirty-five days without discomfort; patient at work on a steamboat! Ulcer entirely healed.

The chief risk in leaving the dressing longer than a week is the liability to set up eczema, which may be quite obstinate, as in the following case:

CASE III.—Thomas M., aged thirty-nine years, cooper.

May 16th.—Has had varicose veins for a long time, and, occasionally, ulcers. The present ulcers have lasted for two weeks. There are three ulcers $\frac{1}{2}$ inch deep, $\frac{1}{2}$ inch in diameter; and six superficial ones $\frac{1}{2}$ inch in diameter. Apply regular boric-acid and crinoline dressing.

23d.—Ulcers improved, but the skin about them is eczematous. Apply iodoform and ung. zinci oxidi.

June 4th.—Redressed every other day. The eczema has disappeared, the ulcers have improved.

Usually there is no pain, and many patients are even able to work and to walk. But in two of our cases the

dressing was not well borne, causing pain for some unknown reason. We give their histories:

CASE IV.—William B., aged thirty-nine years, restaurant.

March 25th.—Has had varicose veins for years, being on his feet over twelve hours a day. He is stout, and his health is good. On the anterior surface of the inferior third of the right leg is an ulcer $\frac{1}{2}$ inch in diameter, $\frac{1}{4}$ inch deep; the base granulating, but dark colored; the surrounding skin pigmented. Apply iodoform powder to ulcer, ung. zinci oxidi over it, absorbent cotton, and regular crinoline bandage.

27th.—Bandage began to pain last night. Remove and apply regular boric-acid and crinoline dressing.

29th.—Bandage again painful. Base of ulcer now level with the skin. Skin somewhat eczematous, and exquisitely sensitive. Apply ung. belladonnæ and ordinary bandage.

31st.—Pain continues. Dress with iodoform and ung. zinci oxidi.

May 14th.—Patient was unable to attend, and has treated himself—with oxide-of-zinc ointment. The ulcer is about the same as when first seen, and very sensitive. Much pain about the ankle.

CASE V.—Matthew D., aged thirty-five years, blacksmith.

February 29th.—Was kicked on the shin February 20th. Now on right leg, anterior surface of middle third, is a superficial ulcer, very sensitive, not granulating. Patient is a rather poorly nourished man, tall, and of large frame. Apply iodoform and ung. zinci oxidi.

March 13th.—Patient irregular in attendance; the treatment remains the same. To-day apply regular boric-acid dressing with ordinary bandage.

17th.—To-day apply the same with crinoline bandage.

19th.—Patient, who walks about all day, has much pain in the ulcer, and thinks the bandage too tight. Redress, putting on the bandage as loosely as practicable. The ulcer is looking well, now $1 \times \frac{3}{4}$ inch.

22d.—The pain and feeling of tightness returned in forty-eight hours. Remove dressing, and apply boric-acid dressing with ordinary bandage.

24th.—Redress; no pain; ulcer looks well.

April 3d.—Patient not seen until to-day. The ulcer has relapsed.

Other dressings may be used with the crinoline bandage. Syphilitic ulcerations do very well with a simple iodoform dressing. Balsam of Peru and other stimulants may be applied, exuberant granulations cauterized, or the ulcers strapped.

The following cases are added to illustrate the methods of treatment and the results:

CASE VI.—Patrick McC., aged forty-four years, laborer.

March 17th.—Has large varicose veins in leg, and a typical varicose ulcer $\frac{1}{2}$ inch in diameter. Wash leg with 1-to-40 carbolic-acid solution, apply balsam of Peru to ulcer, cover it with absorbent cotton, and apply regular crinoline bandage.

25th.—Patient has had no discomfort. Ulcer is entirely healed.

CASE VII.—Thomas McC., aged thirty-one years, truckman.

March 19th.—Has had varicose veins in leg for years. Present ulcer has been of this size for three months. His general health is excellent. On external surface of middle third of left leg is an oval ulcer $1\frac{1}{2} \times \frac{3}{4}$ inch. The edges, rather sharp-cut, rise $\frac{1}{4}$ inch above the base of the ulcer, but are level with the skin; they show no cicatricial action. The surrounding skin is pigmented and bluish. The dark-colored base is covered with

small, torpid granulations. The discharge is abundant and purulent. Apply regular boric-acid and crinoline dressing.

31st.—Has had pain for some days, but did not come. The ulcer is now level with the skin, granulating nicely; but the surrounding skin for 2 inches from the ulcer is eczematous. Apply iodoform and ung. zinci oxidi.

April 2d.—Eczema cured. Apply regular boric-acid and crinoline dressing.

21st.—Redressed on the 9th. Ulcer now closed, except a superficial spot $\frac{1}{4}$ inch in diameter. Redress. Patient did not return.

CASE VIII.—Grace L., aged sixteen (?) years, umbrella-maker.

January 31st.—General health good. Time of syphilitic infection unknown. Two "lumps" formed on her leg "from a blow" two years ago, and five months ago they "broke." Now on middle third of leg over the crest of the tibia are two nodes, apparently arising from the periosteum. The nodes are $1\frac{1}{2}$ to 2 inches in diameter, and rise quite abruptly $\frac{1}{4}$ inch above the general surface. Each node is surmounted by an ulcer 1 inch in diameter, its edges sharp-cut, somewhat undermined, without any inflammatory areola; its base is covered with a whitish adherent layer, and is $\frac{1}{4}$ inch below the edges, but is convex in the middle, the skin having ulcerated over the tumor projecting beneath it. The discharge is watery. The nodes are very painful and sensitive. Ordered: R Hydrarg. bichlor., gr. $\frac{1}{16}$; potass. iodid., gr. v, t. i. d. Apply iodoform and ung. zinci oxidi to ulcers.

February 6th.—Redressed every other day. Surface of ulcers cleaner, nodes smaller. Redress with crinoline bandage.

March 10th.—Has been redressed once a week. Ulcers now $\frac{1}{2}$ inch in diameter, bases level with skin, and granulating; only a slight diffuse swelling is left of the nodes. Ulcers strapped with adhesive plaster. Not seen again.

Book Notices.

Clinical Lectures on Mental Diseases. By T. S. Clouston, M. D. Edin., F. R. C. P. E., Physician Superintendent of the Royal Edinburgh Asylum for the Insane, etc. To which is added an Abstract of the Statutes of the United States and of the Several States and Territories relating to the Custody of the Insane. By CHARLES F. FOLSOM, M. D., etc. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xxiv-33 to 550, inclusive.

The author of this work has long been identified with psychological science in Scotland, and both in his capacity as superintendent of the Royal Edinburgh Asylum for the Insane, and as a former co-editor of the "Journal of Mental Science," has done much for the advancement of the important department of medicine to which so many years of his life have been devoted.

The present work requires no apology; it is written in a clear and lucid manner, and with the evident intention of imparting rather the practical points of the subject than obscure and mooted points in anatomy and pathology. To the student or practitioner who is desirous of acquiring a knowledge of mental disorders and their treatment, but who at the same time is deprived of the opportunities for direct observation afforded by asylums and hospitals for the insane, the book will prove most valuable, embodying as it does not only lucid clinical descriptions, but also an ample array of carefully selected cases.

In many works which pretend to give a systematic clinical history of mental disorders there is often a manifest striving after startling effects, which finds expression in the recital of anomalous and rare cases, which, however interesting in themselves, do not render the descriptions of individual forms of disease more vivid or complete.

We note with pleasure that Dr. Clouston has not fallen into this psychological error. When cases are presented he has been at evident pains to select only such as serve to establish the morphological entity of the particular disease under consideration. As a result of this conservative policy, the mind of the reader is not encumbered with a series of mental monstrosities, but, on the contrary, each morbid type stands forth with a vividness appropriate to its importance. Such a method of writing is both philosophical and practical, and proves beyond question that the author is not only a sturdy thinker, but an accomplished book-maker as well.

BOOKS AND PAMPHLETS RECEIVED.

Lectures on the Principles of Surgery, delivered at Bellevue Hospital Medical College. By W. H. Van Buren, M. D., LL. D. (Yalen.), formerly Professor of the Principles and Practice of Surgery in the Bellevue Hospital Medical College, etc. Edited by Lewis A. Stimson, M. D., Professor of Physiology and Clinical Surgery in the Medical Department of the University of the City of New York. New York: D. Appleton & Co., 1884. Pp. vii-588. [Price, cloth, \$4; sheep, \$5.]

Manual of Chemistry. A Guide to Lectures and Laboratory Work for Beginners in Chemistry. A Text-book specially adapted for Students of Pharmacy and Medicine. By W. Simon, Ph. D., M. D., Professor of Chemistry and Toxicology in the College of Physicians and Surgeons, etc., Baltimore. With Sixteen Illustrations on Wood and Seven Colored Plates, representing Fifty-six Chemical Reactions. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. 411.

The Elements of Physiological and Pathological Chemistry. A Handbook for Medical Students and Practitioners. Containing a General Account of Nutrition, Foods, and Digestion, and the Chemistry of the Tissues, Organs, Secretions, and Excretions of the Body in Health and Disease; together with the Methods for preparing or separating their Chief Constituents, as also for their Examination in Detail, and an Outline Syllabus of a Practical Course of Instruction for Students. By T. Cranstoun Charles, M. D., Fellow of the Chemical Society and of the Royal Medical and Chirurgical and Pathological Societies, etc. Illustrated with Thirty-eight Engravings on Wood and a Chromolithograph. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. 463.

The Science and Art of Surgery. A Treatise on Surgical Injuries, Diseases, and Operations. By John Eric Erichsen, F. R. S., LL. D., F. R. C. S., Surgeon Extraordinary to Her Majesty the Queen, etc. Eighth Edition, revised and edited by Marcus Beck, M. S., and M. B. Lond., F. R. C. S., Surgeon to University College Hospital, etc. With Nine Hundred and Eighty-four Engravings on Wood. Vol. I. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. 1,124.

Medical Rhymes. A Collection, etc., selected and compiled from a Variety of Sources. By Hugo Erichsen, M. D., Professor of Neurology in the Quincy School of Medicine, etc. With an Introduction by Professor Willis P. King, M. D., Sedalia, Mo. Illustrated. St. Louis, Chicago, and Atlanta: J. H. Chambers & Co., 1884. Pp. xx-220.

Report of the Commissioner of Education, for the Year 1882-'83. Washington: Government Printing-Office, 1884. Pp. cccxiii-872.

Lectures on Diseases of the Rectum, delivered at the Medical Department of the University of the City of New York. By J. Williston Wright, M. D., Professor of Surgery. New York: Bermingham & Co., 1884. Pp. 170. [Price, \$1.25.]

Medical Diagnosis. A Manual of Clinical Methods. By J. Graham Brown, M. D., Fellow of the Royal College of Physicians of Edinburgh, etc. Second Edition, Illustrated. New York: Bermingham & Co., 1884. Pp. 285.

The Principles and Practice of Midwifery, with Some of the Diseases of Women. By Alexander Milne, M. D., Ex-Vice-President, Edinburgh Obstetrical Society, etc. Illustrated with Numerous Wood Engravings. Second Edition. New York: Bermingham & Co., 1884. Pp. 371. [Price, \$2.]

Diseases of the Nose. By Clinton Wagner, M. D., Professor of the Diseases of the Nose and Throat in the New York Post-Graduate Medical School, etc. With Illustrations of Instruments and Pathological Conditions. New York: Bermingham & Co., 1884. Pp. 252. [Price, \$2.50.]

A Manual of Dermatology. By A. R. Robinson, M. B., L. R. C. P. & S., Edin., Professor of Dermatology at the New York Polyclinic, etc. New York: Bermingham & Co., 1884. Pp. 647. [Price, \$5.]

London Water Supply. Report, etc., No. xlv.

The Medical Record Visiting List, or Physicians' Diary, for 1885. New York: William Wood & Co.

A Contribution to the Clinical Study of Rötheln, or German Measles. By W. A. Edwards, M. D., etc. [Reprint from the "American Journal of the Medical Sciences."]

On Branchial Cysts of the Neck. By N. Senn, M. D., Milwaukee, Wis. [Reprint from the "Journal of the American Medical Association."]

New York State Medical Association. Constitution and By-Laws, adopted 1884.

Minutes of a Convention held in the City of Albany, February 4 and 6, 1884, at which the New York State Medical Association was organized on a Permanent Basis.

Catalogue of Members of the Medical Profession in the State of New York, showing their Vote on the Codes of Ethics. Corrected Edition. Published by the Central Organization of the New York State Medical Association to uphold the National Code of Ethics.

New York County Medical Association. By-Laws, adopted January 14, 1884.

Annual Report of Marc Livingston, M. D., Coroner of the City and County of San Francisco, for the Fiscal Year ending June 30, 1884.

Kentucky School of Medicine. Twenty-ninth Annual Announcement, Session of 1885.

Announcement of the Regular Session of 1885 of the Hospital College of Medicine, Medical Department of Central University, Louisville, Ky.

Explanation of the Pathology and Therapeutics of the Diseases of the Nerve Centers, especially Epilepsy. By J. McF. Gaston, M. D., Atlanta, Ga. [Advance sheets from the "Transactions of the Medical Association of Georgia."]

The Sheltering Arms. Twentieth Annual Report, New York, 1884.

Annual Report of the Secretary of the Navy for the Year 1883. In two volumes. Volume II. Sanitary and Statistical Report of the Surgeon-General of the Navy for the Year 1882. Washington: Government Printing Office, 1884.

Disorders Mistaken for Hydrophobia. By Charles W. Dulles, M. D., etc. [Extracted from the "Transactions of the Medical Society of the State of Pennsylvania," for 1884.]

Mental Contagion in Inebriety—a Psychological Study. By T. D. Crothers, M. D., Hartford, Conn.

NEW YORK, SATURDAY, NOVEMBER 8, 1884.

AMERICAN PRACTICE IN ABDOMINAL SURGERY.

If we are ever to see the last of the comparatively unfavorable results of laparotomy in this country, it must be by means of efforts guided by something approaching certain knowledge of the cause or causes of our present shortcomings. It looks as if those causes were even now within the ken of a few of our most experienced operators, but it is quite certain that there is nothing like a general recognition of them, or even a concerted search for them. Suggestions are made now and then, to be sure, but for the most part they are promptly shown to be groundless. It is manifest, for instance, that Mr. Lawson Tait shot wide of the mark in his clinical lecture to the students at Bellevue Hospital some weeks ago, which we published in our issue of October 18th. It will be remembered that on that occasion Mr. Tait could suggest no other reason for our bad showing than the fact that there were too many men engaged in the work. No doubt that is "an o'er true tale," and it might go far toward explaining the tenor of our total statistics, but it is quite obvious that it counts for nothing as an explanation of the fact that our leading operators—men who are no novices in abdominal surgery, and whose technical skill is beyond question—fall behind the best-known laparotomists of Great Britain.

We are not at all sure that something very like the reverse of Mr. Tait's reason may not lie at the root of our unsatisfactory figures. Not that we have any idea that there are too few American surgeons who essay laparotomy, for we agree decidedly with Mr. Tait that there are too many; but we will put it a little differently, and say that there are too few localities, and those localities too close together, where men skilled in abdominal surgery are to be found. Except for the brilliant achievements of a few men in limited spheres, it is to the surgeons of the Woman's Hospital that the sufferers with ovarian tumor have looked as the ministers of their last desperate chance of relief. There is nothing strange in this; it was in this city that the gynecology of the present day practically had its birth, and for several years ours was the only hospital in the world devoted wholly to the treatment of the diseases peculiar to women. Consequently, New York has been the place to which women with ovarian tumors have resorted, whether they lived three miles away or three thousand. It is easy to understand that those who were compelled to come a great distance were prone to put off the evil day as long as possible, being treated in the mean time by palliative measures which, especially tapping, only tended to reduce their chances in the end. This amounts to saying—what we said on a former occasion—that our surgeons have had to battle against an undue proportion of bad cases. That this is a fact there can be no question. Most

of our New York ovariologists are familiar with the work of their European brethren by repeated and continuous observation, and it is their decided conviction that nowhere else are so many unpromising cases seen as at the Woman's Hospital.

If there is any truth in these reflections—and we are convinced that they embody a most weighty truth—it will be a happy day for American ovariologists when it can be said that the services of an experienced operator are within easy reach of every woman. Patients will then more generally subject themselves to operation early, because they can do so at comparatively little sacrifice, and our New York surgeons, no longer handicapped with so many desperate cases, will be enabled to make a record more truly expressive of their capabilities. That that day is not far distant there is reason to hope from such experiences as Dr. Sutton, of Pittsburgh, was able to relate at the recent meeting of the American Academy of Medicine, a report of which will be found in this issue of the journal. So impressed is Dr. Sutton with the danger of tapping that he suggests a means of putting a stop to the practice which must certainly be called radical—that of a general refusal on the part of surgeons to operate on patients who have been subjected to tapping. However justifiable such a refusal might be from a theoretical point of view, we take it for granted that in his practice Dr. Sutton, like other American ovariologists, never denies a patient the slight chance of relief that the operation may hold out, no matter how likely her case may be to spoil his statistics. That is the only conscientious course to pursue, even at the risk of continuing our relatively unfavorable results.

FEMALE INTERNES IN THE PARIS HOSPITALS.

THE question of the admission of women to the *interne* is just now agitating some of our brethren in Paris, and the "Gazette hebdomadaire" publishes a letter on the subject which is rather entertaining. The writer makes a strong stand against the despised sex. He reviews the arguments (if a series of disconnected statements can be called arguments), and then indulges in a lofty flight of imagination, picturing the dreadful effects of the slightest concession to feminine appeals. Some of his objections to female house officers are amusing. First comes the moral argument; mention is made of the countless "inconveniences" that would result to the visiting staff from the introduction of *un démon tentateur* into their wards. It strikes us that this is an unwarranted reflection on the moral stamina of the prominent members of the Paris profession. Again, the fear is expressed that, since the *interne* is placed in most intimate relations with his superior, the latter "could not see without a certain embarrassment a young woman attached to his steps, desirous of following him everywhere, of rendering to him in every case, and on every occasion, the assistance which a faithful *interne* owes to his affectionate master." What peculiar occupations French *internes* may have, over and above their professional work, we do not know, but, at all events, it would be cruel for any young woman to embarrass her chief in the line of duty.

The objection is seriously urged that "the patients them-

selves would suffer during the female *internat*." This assertion is not supported with explanations, but is assumed to be incontrovertible. The cruel position of a "bearded *externe*," when subjected to the tyranny of a "blonde *interne*," is feelingly alluded to. Of course this argument is beyond appeal. But the home-thrust is contained in the remarkable statement that no woman could hold such a position, because the performance of her menstrual function would incapacitate her for continuous work. The idea does not seem to have occurred to the writer that the same objection might hold good in the case of the nurses, whose duties are scarcely less severe and unremitting than those of the house staff.

We have little further comment to make on this flippancy treatment of an important question, and it is not our intention to enter upon a discussion of the fitness of women to study and practice medicine under the same conditions that are imposed upon men. That the writer in question has treated the subject from a low standpoint is undeniable; but, since he has chosen to consider its moral and sentimental aspects, it is a pity that he has not displayed more of that chivalry, if not respect, for the other sex which marks at least the outward conduct of his countrymen. He is an alarmist of the most pronounced type. "*Cet interne en corsage*," he remarks satirically, "*s'il se montre supérieur, vous en ferez, j'espère, un chef de clinique*." He traces the course of the daring girl as she rises step by step, and finally knocks audaciously at the portals of the sacred *Académie*. Then, in his grand climax of irony, he raises her to the Senate itself; "and this," he says, "is how the great question of the emancipation of woman is entirely contained within this little egg of the *internat des hôpitaux*."

Although prepared, by our own political experience, to sympathize with the writer in this latter fear, we do not look for quite such a sequence in his country. At any rate, the experiment is not so dangerous as not to be worth trying, and, for our part, we should not be sorry to see it made, at least on a limited scale. There is ample room for improvement in the condition of French women, and, if they have the courage and the ability to attain to an honorable position in the medical profession, Heaven forbid that they should be opposed for such trivial reasons as those set forth by this writer.

MINOR PARAGRAPHS.

THE RHINELANDER LUNACY CASE.

RECORDER SMYTH, of the Court of General Sessions, has decided that William O. Rhinelanders is sane and must plead to the indictment charging him with a murderous assault on Mr. John Drake, at his office, in Cedar Street, last June. The decision in this case has been awaited with a good deal of interest for many reasons. It will be remembered that Rhinelanders himself has asserted from the beginning that he was entirely sane, and that the allegation that he was insane was made by his family, with whom he was not on good terms, in order to avoid the disgrace of a criminal trial. When the statement was made, shortly after the shooting, that he was insane, the Recorder appointed a commission, consisting of Dr. William Detmold, Mr. Patterson, and Mr. Nolan, to examine into the matter and report to the Court.

After a very exhaustive examination, one of the commissioners (Mr. Patterson) reported that the man was sane, and the two others (Dr. Detmold and Mr. Nolan), that he was insane. Upon this latter report a motion was made to commit Rhinelanders to a lunatic asylum. This motion Recorder Smyth has just denied, holding that, under a proper construction of the Code of Criminal Procedure, the report is only for the information of the Court, and can be adopted or dismissed. Having asserted this liberty of choice, he accepts the report of the single commissioner, Patterson, and adjudges Rhinelanders to be sane. As a result, the latter has just been admitted to bail in the sum of \$10,000, and the trial will be had in a short time.

The whole proceeding is mainly of interest as showing the advantages of the new method over the old one in trying issues of insanity. Formerly they were decided when the prisoner was on trial, and so many other points were always involved that the issue of insanity did not receive the careful scientific attention it deserved. Under the new code, no question as to the alleged criminal's sanity can be raised on the trial, but must be decided by itself before he is called upon to plead to the indictment. Recorder Smyth is quite contemptuous in his criticisms of the expert testimony adduced, his words being as follows: "I agree with the learned commissioner, Patterson, that the expert evidence is of no value in this investigation. While the physicians called by the people to sustain the allegation of insanity say that the defendant is insane, they differ radically among themselves as to the classification of that alleged insanity. Two say that he has general paresis; one says that he is an imbecile; and another that he suffers from melancholia. He can not have all these conditions at one and the same time; insanity in its initial stages and in its progressed stages can not coexist in the same person. . . . There is a singular deficiency of evidence of positive facts indicating insanity, and, as the learned Dr. Detmold says, in his opinion, the expert evidence is 'rather weak.' The record before me fully justifies the conclusion of Commissioner Patterson, 'that the defendant is a nervous, impulsive, and self-willed person.'"

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 4, 1884:

DISEASES.	Week ending Oct. 28.		Week ending Nov. 4.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	60	11	41	22
Scarlet Fever.....	31	4	33	1
Cerebro-spinal meningitis....	4	4	3	3
Measles.....	41	3	52	10
Diphtheria.....	45	28	63	36

The West Virginia Medical Practice Act.—On the 1st inst. the Court of Appeals of West Virginia delivered its opinion that the law regulating the practice of medicine and surgery was constitutional and valid. This decision, we are glad to say, at once places the State Board of Health on substantial legal ground.

The Chicago Gynecological Society held its annual meeting on the 31st of October, at the house of the retiring president, Dr. A. Reeves Jackson, who, in accordance with long-established custom, entertained the members with an elaborate banquet. The following-named gentleman were elected officers for the ensuing year: Dr. H. P. Merriman, president; Dr. E. C. Dudley, first vice-president; Dr. Charles Warrington Earle, second vice-president; Dr. Edward Warren Sawyer, secretary

and treasurer; and Dr. W. W. Jaggard, editor. After an appropriate address by the retiring president, the society adjourned, to meet on Friday, November 21st, when a discussion on "The Premature Expulsion of the Ovum" will be opened by Dr. Edward Warren Sawyer.

The Health of the State of New York.—By the monthly bulletin issued by the State Board of Health, covering the month of September, we learn that the total reported mortality for the month was 6,947. The percentage of infant mortality was 43.2, of that from diarrhoeal diseases 21.2, of that from croup and diphtheria 3.2, of that from typhoid fever 2.3, of that from acute respiratory diseases 6.7, and of that from consumption 12.5. About half the entire mortality was reported from the four cities of New York, Brooklyn, Rochester, and Albany, having an aggregate population of 2,200,000. They showed an infant mortality of about 48 per cent. The returns from Buffalo and Watertown, as well as those from many of the larger villages, had not been received.

A Sanitary Convention will be held at East Saginaw, Mich., on Tuesday and Wednesday, December 2d and 3d, under the auspices of the State Board of Health. The objects of the convention are stated to be the presentation of facts, the comparison of views, and the discussion of methods relating to the prevention of sickness and death, together with the improvement of the condition of the living. An invitation is especially extended to health officers to be present and take part in the discussions. The Michigan board must certainly be doing an excellent work in thus providing for the instruction of local sanitary officers and the people at large in matters relating to the public health.

Changes in the Canadian Faculties.—The "Canadian Practitioner" announces that Dr. Carson has been appointed lecturer on botany in the Woman's Medical College of Toronto, and that Mr. Thomas McKenzie, B.A., has been appointed lecturer on botany and zoology in the Toronto School of Medicine, in place of Mr. H. Montgomery, who is now in Dakota.

The Brooklyn City Hospital Training School for Nurses held its third annual commencement Tuesday evening, October 28th, when diplomas were awarded to eleven graduates. Dr. Alexander Hutchins delivered an excellent address to the graduating class.

The Bridgeport Hospital will be inaugurated on Tuesday, the 11th inst. The order of exercises issued by the Committee of Arrangements includes an address by Dr. D. B. St. John Roosa, of New York.

The Sanitation of Naples, according to the "Medical Times and Gazette," is to be prosecuted vigorously. A wide street is to be carried through the most perilous quarters, and new accommodations are to be provided for the operatives. The destruction of houses found to be insanitary, as well as that of wells and cisterns, is promised, and it is to be the duty of the municipality to see to it that none but pure water is used.

The Death of Dr. Edward F. Arnoux, of Fort Lee, N. J., is announced to have taken place on Wednesday, October 29th. Dr. Arnoux was a graduate of the old New York Medical College, of the class of 1855.

The Alumni Association of the College of Physicians and Surgeons.—At a recent meeting of the Councilors, suitable resolutions were adopted expressing the thanks of the association to Mr. Vanderbilt for his gift to the college, and measures were suggested for supplementing the endowment with additional funds to be devoted to special purposes.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 26, 1884, to November 1, 1884:*

ALDEN, C. H., Major and Surgeon. In addition to his duties at Fort Snelling, Minn., to perform the duty of attending surgeon at Department Headquarters. S. O. 127, Headquarters Department of Dakota, October 23, 1884.

TOWN, F. L., Major and Surgeon. Assigned to temporary duty as post surgeon, Fort Clark, Texas. S. O. 145, Department of Texas, October 27, 1884.

BENTLEY, EDWIN, Major and Surgeon. To be relieved from duty at Fort Clark, Texas. S. O. 145, Department of Texas, October 27, 1884.

WILSON, W. J., Captain and Assistant Surgeon. Assigned to temporary duty at Fort Trumbull, Conn. S. O. 220, Department of the East, October 27, 1884.

CORBUSIER, W. H., Captain and Assistant Surgeon. Assigned to duty at Fort Bowie, Arizona Territory. S. O. 99, Department of Arizona, October 23, 1884.

LA GARDE, L. A., Captain and Assistant Surgeon. Assigned to duty at Fort Ellis, Montana Territory, relieving First Lieutenant G. E. Bushnell, Assistant Surgeon, U. S. A., who, upon being relieved, will report for duty at Fort Snelling, Minn. S. O. 126, Department of Dakota, October 22, 1884.

EVERTS, EDWARD, First Lieutenant and Assistant Surgeon. Leave of absence extended one month. S. O. 107, Headquarters Division of the Pacific, October 21, 1884.

McCaw, WALTER D., First Lieutenant and Assistant Surgeon. Ordered from Fort Craig, New Mexico, to Fort Wingate, New Mexico, for duty. S. O. 92, Headquarters District of New Mexico, October 21, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 1, 1884:*

BEARDSLEY, GROVE S., Surgeon. To Washington, D. C., for examination preliminary to promotion and as to qualifications for sea duty, October 31, 1884.

CRAIG, THOMAS C., Passed Assistant Surgeon. Ordered to the Alliance for temporary duty, October 31, 1884.

GARDNER, JAMES E., Passed Assistant Surgeon. Ordered to the Naval Hospital, Norfolk, Va., October 28, 1884.

HALL, JOHN H., Passed Assistant Surgeon. Relieved from the Naval Hospital, New York, and ordered to the Navy-Yard, Mare Island, Cal., October 29, 1884.

HORD, WILLIAM T., Medical Director. To continue duty as member of the Retiring Board until January 1, 1885. October 27, 1884.

LOVERING, P. A., Passed Assistant Surgeon. Ordered to the Naval Dispensary, Washington, D. C., for temporary duty, October 27, 1884.

TURNER, THOMAS J., Medical Director. To continue duty as member of the Retiring Board until January 1, 1885. October 27, 1884.

STEELE, JOHN M., Passed Assistant Surgeon. Ordered to the Naval Hospital, New York, October 29, 1884.

Society Meetings for the Coming Week:

MONDAY, November 10th: New York Ophthalmological Society (private); New York Medico-Historical Society (private); Chicago Medical Society; Boston Society for Medical Improvement; Gynecological Society of Boston; Burlington, Vt., Medical and Surgical Club (annual); Norwalk, Conn., Medical Society (private).

TUESDAY, November 11th: New York Surgical Society; New York Medical Union (private); Medical Societies of the

Counties of Rensselaer and Ulster, N. Y., Camden, N. J., and Fairfield, Conn. (Bridgeport); Newark, N. J., Medical Association (private); Trenton, N. J., Medical Association (private); Norfolk District, Mass., Medical Society (Hyde Park); Penobscot County, Me., Medical Society (Bangor).

WEDNESDAY, November 12th: New York Pathological Society; American Microscopical Society of the City of New York; New York Medico-Legal Society; Medical Society of the County of Cayuga, N. Y.; Worcester, Mass., District Medical Society; Pittsfield, Mass., Medical Association (private).

THURSDAY, November 13th: Harlem Medical Association; Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; South Boston, Mass., Medical Club (annual—private).

FRIDAY, November 14th: Yorkville Medical Association (private); Medical Society of the Town of Saugerties, N. Y.

Letters to the Editor.

A CASE OF REFLEX PARALYSIS.

SULPHUR SPRINGS, TEXAS, September 22, 1884.

To the Editor of the *New York Medical Journal*:

SIR: On the 17th inst., early in the evening, I was called hurriedly to see Alice, a girl of about thirteen years, who lives just across the street from me, and found her sitting in a chair, with her hands and feet cold, and the tongue twisted, in the shape of a corkscrew, to the left, and protruding from the mouth. She was unable to articulate distinctly, the pupils were somewhat dilated, and the history was that she had been well up to the moment the paralysis of the tongue came. She had eaten an ordinary dinner, in the evening she ate an apple, and, about ten or fifteen minutes before she was taken, several pieces of candy, commonly called gum-drops, colored red. Her pulse ran down so low that she looked as if she would die in a few minutes. Thinking that it was a case of poisoning, I gave an emetic of mustard in warm water, and caused her to drink copiously of warm water until free emesis followed, when, by the use of a sinapism to the spine, she reacted very well, the pupils responded to light, and to all intents she seemed well and rational, with the exception of the tongue, which continued twisted as badly as ever, but gave no inconvenience except in swallowing solid food. I will say that, in vomiting, she threw up her dinner, still undigested, with the apples and candy. I gave ten grains of calomel, and followed it in two hours with castor-oil. Was this paralysis of the hypoglossal nerve, caused by reflex action resulting from a torpid liver? I forgot to state that the bowels had not moved in twenty-four hours prior to the time she was taken. On the morning of the 13th I repeated the calomel, which did not act until the 20th, at twelve o'clock, when the paralysis gave way, but with the disposition remaining to twist when the tongue was protruded precipitately. This morning the paralysis has entirely subsided, and she seems as well as ever. I will say, in conclusion, that Dr. Doney and Dr. Dial saw the case with me, and agree with me in this, that they never saw or heard of anything similar to it before. I can find no literature that satisfies me on the subject. If this is worth anything to the profession, and you see proper, you can publish the same.

Yours truly,

J. M. HOOPER, M. D.

P. S.—She menstruated for the first time just one week prior to the date of this attack. She had no inconvenience whatever attending it.

Proceedings of Societies.

AMERICAN ACADEMY OF MEDICINE.

Ninth Annual Meeting, held in Baltimore, Tuesday and Wednesday, October 28 and 29, 1884.

The President, Dr. BENJAMIN LEE, of Philadelphia, in the chair.

Tuesday's Proceedings.

THE meeting was called to order in the afternoon, at Johns Hopkins Hall, and the proceedings were opened with a prayer by the Rev. J. E. GRAMMAR, D. D.

The minutes of the last meeting and the report of the Council were read and approved. Forty-one new members were elected, and a Committee on Nominations was appointed.

The Relation of the Medical Colleges to Preliminary Education was the title of a paper by Dr. PETER D. KEYSER, of Philadelphia, who analyzed the Report on Medical Colleges as given in the Fifth Annual Report of the State Board of Health of Illinois, and concluded that but few of the ninety-one medical colleges actually insisted upon any definite knowledge of the students' preliminary training before entering upon the study of medicine.

The Examination of Applicants for License to Practice a Means of raising the Standard of Medical Education was the title of the next paper, read by Dr. EDWARD JACKSON, of Philadelphia, who advocated the necessity of an independent board of examiners, whose certificate would be the only credential necessary for practicing. By this means the demand upon the colleges would be for men who would be able to pass the State examination, and, as a consequence, the inefficient would be "plucked" by the faculty for the fame of their institution.

These papers elicited considerable discussion, showing that the opinion of the fellows coincided with the views of the essayist.

The Role of Bacteria in Infectious Diseases was the title of the third paper, by Dr. HENRY O. MARCY, of Boston, who referred to the great importance of the subject to medicine, whether in relation to its theory or its practice, and to the great amount of literature already issued upon the subject, giving as the reason of this additional contribution the conclusions reached by a lecturer in Boston during the past year, w.l.o., in a series of semi-popular lectures, asserted that even fermentation was not caused by the development of a low order of vegetable organisms. This statement was based on the assertions that the micro-organisms in any series of experiments had never been separated from the "ambient living matter," which must be considered of a low degree of inherent vitality, and that, until a well-washed micrococcus or bacillus had been isolated upon the point of a needle and then introduced into a sterilized nutrient solution, the conditions of the problem would not have been fulfilled. Since anything might be doubted, and science was only pure, simple truth, and never suffered from test, the essayist had determined to put the matter to the test. Dividing the objection into that regarding the "ambient living matter" and that relating to the germ, and recognizing the "ambient living matter" as the bioplasm of Beale, which, it was admitted, had inherent vital power (and possibly in the blood of a healthy animal this vital power would be shown if anywhere), the following experiments had been made, to determine the bioplastic power of protoplasmic matter. The blood of healthy sheep and oxen was taken, with careful precautions, and, as soon as the clot had separated, sterilized glass bulbs were filled and sealed by the flame; and others, charged with sterilized culture fluids, were inoculated in varying proportions. These were kept for

different periods of time, subject to the same conditions as in the growth and testing of various bacterial organisms, and careful examinations made at different dates with a Zeiss one-fourteenth objective, giving an amplification of about one thousand diameters. Only in one of twenty bulbs did any change take place, and this, upon its first opening on the third day, remained sterilized. Albumen from an egg still warm from the nest, milk aseptically drawn and put up at once, and the aqueous humor, were also thus tested. In a series of forty-one bulbs, only two contained bacteria and micrococci, which evidently were accidentally introduced. It seemed fair to deduce that this "ambient living matter" possessed no power of reproduction, which indeed had usually been assumed in investigations of this character.

No one at the present time denied the importance of these micro-organisms, or the relation they sustained to disease. Whether that relation was one of cause and effect could be demonstrated in the class of zymotic diseases. In this case medicine would have at least a scientific foundation. But, while science was "pure and simple," a very difficult problem presented itself where generalizations were attempted. But generalizations might be possible in the near future, from the accumulation of facts by many independent investigators. To demonstrate the action of the micro-organism it must be separated from everything else, whether "liquid ambient matter" or chemical poison, having relation to the disease.

This organism, thus separable, must, upon inoculation in the tissue of a healthy living animal of the same species, cause a reproduction of the disease. To separate the micro-organisms fully, the process of pure culture had been devised, in which, as in some of Dr. Sternberg's experiments, in the eighth culture the proportion between the original matter and the amount of culture fluid could only be expressed by figures representing quadrillions; and yet a few minims of this eighth culture possessed all the virulence of the first.

Again, if the septic material acted by chemical changes, it should act rapidly, or, being eliminated, recovery should ensue, which was not the fact. For, if the animal died, it was never until time enough had elapsed for the reproduction and growth of micro-organisms, which, upon examination, were found in the tissues. The way in which bacteria produced death was probably by a combination of several processes, so that it was made a difficult study from the complexity of vital equations.

There were many questions relating to the subject which we must for the present, and perhaps for all time, remain ignorant about, as, for example, how certain forms of infectious disease produced immunity from a subsequent attack of the same. The various diseases in which bacilli or micrococci had been demonstrated more or less clearly were enumerated with some detail. It was to be concluded from this review that the time had passed when the critic of the germ-theory of disease could content himself with captious remarks upon "fashion in medicine," etc. In this direction science was not without its martyrs; the investigation of the cholera in Egypt and India and of yellow fever in Havana was not less dangerous than an expedition to discover the sources of the Nile or in quest of the Northwest Passage.

The Trade Aspect of Medicine was the title of a paper by Dr. A. L. GIBON, of the navy. It treated first of the tendency of many to degrade the profession of medicine to a mere trade. Among the ninety thousand physicians of the country there were mechanic surgeons, men midwives, and trade doctors, and had they a right to the honor and consideration that pertained to the other members of the profession of medicine? If not, how could the fact be made patent?

Not long ago there was a complaint, voiced in a communi-

cation to one of our medical weeklies, because an army surgeon happened to treat patients in civil life, and thus deprived a civilian of a possible fee. There the trade spirit was shown ingrafted on a noble stock, which it threatens to overrule and cause to bear only its own unsavory fruit. The correspondent wrote as he felt, and he felt as the corner grocer felt whose gall was stained because some other vender had cut down his sales by offering better or more tempting wares.

The trade physician made everything bend to practice—there was no danger that he would favor boards of health, or look with complacency upon preventive medicine. Even in society meetings the section of State medicine was not a sufficiently coated pill for him to swallow; but he was anxious to learn of some formula good for a given disease. Even some medical societies (not all, but some) had become mere trade unions, as was proved by their using a fee-bill. Truly, such men did not belong to the profession, but how were they to be kept out of it? Attempts at exclusion of various kinds had failed; educational acquirements, while meaning something, would not exclude all of them. The remedy lay in the profession itself. But what constituted the profession? Was it a tri-unity of science, art, and trade? Colleges failed, societies failed, there remained but a separation of those who clung to the tradesmen and those who did not.

But there were beams in our own eyes—we were not all willing to say we did not know, or to refuse a fee from one who should use it for bread; to use hygienic measures rather than drugs where hygienic measures would answer. To these and other counts we must frequently plead guilty. But, if all this was done, how could men who made medicine their profession live? In the first place, a higher standard would decrease the number entering the profession. Hospitals and dispensaries should be largely increased in number, and the young graduate, instead of being obliged to wait, should be able to enter upon the service of one of these hospitals where he would receive an assured salary. This would give employment to a large number of physicians, secure better treatment of the poor than the nostrum so often employed, and give an opportunity for the accurate collection of statistics.

Differentiation the Test of Civilization; the Specialist and his Education (the President's Address).—At the evening session, the PRESIDENT read his address, Vice-President GIBON having been called to the chair. He referred to the medical history of Maryland, quoting from the earlier records, to show that the commonwealth was early alive to the qualifications of practitioners, even of specialists. Then, touching on the principle of division of labor, he spoke of the result brought about by such a division in the medical profession, not, however, without the opposition of many men in the profession. He recounted in order the arguments pro and con used in opposition to and in favor of specialism, and concluded that the specialist had come, and he had "come to stay." The education necessary for the training of a specialist was then taken up and discussed.

Wednesday's Proceedings.

Honorary Members.—The Council recommended that Dr. GEORGE M. STERNBERG, of the army, and Dr. OLIVER WENDELL HOLMES, of Boston, be elected to honorary membership, which was done. Four additional fellows were also elected, making forty-five in all.

Election of Officers.—The following-named gentlemen were elected as the officers for the ensuing year: Dr. ALBERT L. GIBON, of the navy, president; Dr. R. STANSBURY SUTTON, of Pittsburgh, Dr. JAMES A. STEWART, of Baltimore, Dr. WILLIAM ELMER, of Bridgeton, N. J., and Dr. J. CHESTON MORRIS, of Philadelphia, vice-presidents; Dr. RICHARD J. DUNGLISON, of Phila-

delphia, secretary and treasurer; Dr. CHARLES MCINTIRE, JR., of Easton, Pa., assistant secretary.

The Induction Coil; its Varieties and the Differential Indications for their Use.—Dr. A. D. ROCKWELL, of New York, read a paper with this title. Two kinds of electro-magnetic machines had been presented to the profession, the separate and the continuous coil. These were explained by means of diagrams, and a preference was expressed for the continuous coil. With this form of machine it was possible to have ten different combinations, but, after much experience and observation, he had found that three of these possessed all the properties that could be obtained from them all. These were: 1. The current obtained from the primary coil, of large quantity and small tension. It was of considerable power—it would burn iron wire and could be used for electro-plating. It had but slight power of causing contractions of the muscles in health, but in some pathological conditions would produce muscular contractions far exceeding in vigor those that were called forth by the stronger induction coils. This current would relieve true neuralgia of the head better than other induction coils. In cases of asthenopia, the tired eye was relieved, and by its continuous use strengthened; it was also employed to relieve annoyance from *musca volitantes*. 2. A combination of the primary with the first and second induction coils, which gave a current of peculiar and unique character. It would electro-plate, but would not burn steel. It had the maximum power of producing muscular contraction, but each additional coil decreased this power—why, it was difficult to say. The current was not at all pleasant, and was called for where a powerful impression was required; hence, in not a few cases of paralysis where the response to galvanism was perfect, but where there was a diminution of the farado-muscular contractility, this current is better than any other. In superficial forms of anæsthesia it was, perhaps, in no way superior; but in certain persistent forms of lost or perverted sensibility it was better than any other form. 3. The primary, in connection with the first, second, and third induction coils, made an interesting and important combination. It was tonic and sedative. Its range was wider than those of the others, and it was useful in general faradization. The best constitutional effects were brought about by this form, and it acted in relieving that great army of symptoms shown in general neurasthenia. The action on the motor and sentient nerves was less severe, and its general effects were more agreeable.

In the absence of Dr. V. P. GIBNEY, of New York, his paper, on "Some Comparative Results of Treatment of Chronic Articular Osteitis of the Hip," was read by title only and referred to the Council.

The Place of the Physician in Literature was the title of the next paper, by Dr. C. C. BOMBAUGH, of Baltimore. This place was active where the physician was writing, and passive where he was written about. It was to this latter form that the paper referred, showing, by quotations from the whole range of literature, the esteem or contempt in which the profession had been held, and showing that in many instances satirists had had only too good reason for their satire. If these writings had been accepted in good faith, and acted upon, it would have been of great help in ridding the profession of some of its follies.

Observations on One Hundred and Thirty-seven Abdominal Sections was the title of a paper by Dr. R. S. SUTTON, of Pittsburgh. These observations were founded upon various operations in America and Europe, twenty-nine of them by the writer, comprising the various forms of abdominal section. Most of the ovariectomies had been done upon a comparatively poor class of patients, and in the United States the rule had been to operate after the health of the patient had been broken, and to operate at her home. In England, Scotland, and Germany

early ovariectomy in a special hospital was recommended, while in Austria the patients were not seen so early, and the operation was performed in the general hospital, where the results were not so good. There was a time in every case of ovarian tumor where there were no adhesions, and the operation was then almost free from danger. If, by neglect of the patient or bad medical practice, she was tapped and persuaded to wait until death stared her in the face, the risks from the operation were greatly increased. He had been gradually approaching three conclusions: 1. Nearly all patients with ovarian cyst recovered if operated on early and with proper precautions. 2. A very large number would die, if operated on in their own homes, under ordinary precautions. 3. Simple cases and a well-regulated special institution for the work would always be the mainspring of success in the operation. An ovariectomy done early was one of the easiest of surgical operations, but a neglected case was a very different affair. After the operation was completed, a most important matter was to leave the peritoneal cavity dry. As a rule, the younger subjects did best, but older ones bore the operation well. Climatic influence had very little effect. The details of antiseptic precautions need not be carried out, but one must "wash and be clean." Methods of operating differed very much. The simpler methods were preferable. The prevention of loss of blood was of the greatest importance. In supra-vaginal hysterectomy, the question of the disposition of the pedicle was still *sub judice*—where a cyst was multilocular, a trocar should be used, and as the cysts were emptied the abdomen should be filled with sponges, to protect the intestines from chill. Adhesions were best treated by ligation and division with Paquelin's cautery. The best outside dressing after hysterectomy, if the stump was left outside, was iodoform gauze. Drainage in intra-abdominal operations should be resorted to only in cases where it was not certain that the bleeding had all been arrested, where many adhesions had been divided without the cautery, and when the peritonæum was so irritated that it was almost certain to throw off much serum.

Wet instruments were more comfortable, and taking them directly from the bath, and replacing them until they were needed again, insured cleanliness. The best appliance for arresting hæmorrhage was Kæberle's hæmostatic forceps. While modes of operating differed widely, simplicity and care in the details of preparation and finishing were two very important points.

Dr. Sutton took the following steps in his own operations: Preparation of the room in which the patient was to be operated on, of the instruments and sponges, of the patient herself, of the nurses, and of the operator and his assistants. Care was taken as to the admission of spectators. The room contained only a bed, a table, and a chair, well washed and treated with a solution of mercuric chloride (1-2,000). The instruments were scrupulously cleansed, the patient was given a laxative dose thirty hours before the operation, and a complete washing on the morning of the operation. She ate her breakfast as usual, and only knew of the approach of the operation by her not being furnished with her dinner. The nurses, operator, and assistant all took a bath and put on fresh clothes previous to the operation, and all their hands were washed in oil of turpentine. He used two nurses and one assistant. Spectators were limited to three, and they were not allowed to touch anything. They were obliged to leave their coats in the hall. The patient was anæsthetized by the nurse, and carried on a board to the table, firmly secured, and having a can of hot water placed at her feet. The region of the operation was the only part exposed, the rest of the abdomen being covered with a rubber sheet, over which were placed towels wrung out of hot water. The instruments were lying in a bath of hot water and the sponges were steam-

ing in a double bucket ready for use. The operation was done slowly and with extreme care.

Abdominal operations were growing in frequency every year, and, after excluding pregnancy, renal disease, and heart disease, very little attempt was made at a diagnosis until after the section. He strongly urged the selection of cases for operation, since it was so common a habit to tap, and each tapping rendered the success of an inevitable operation more doubtful. If surgeons would refuse to operate in these cases, the habit of tapping would soon be given up, and better results might be expected. The most important point now under consideration in abdominal work was the place in which the operation should be done. Thus far, hospital statistics gave the best results.

At the conclusion of Dr. Sutton's paper the Academy took a recess and visited the chemical and biological laboratories of the Johns Hopkins University. After this there was a spirited discussion upon Dr. Sutton's paper, participated in by Dr. W. TABOR JOHNSON, of Washington; Dr. E. H. M. SELL, of New York; Dr. H. O. MAROT, of Boston; and Dr. H. P. C. WILSON, of Baltimore. The views expressed in the paper were generally agreed to, the chief exception being the opinion that a surgeon should never refuse to operate while there was a ghost of a chance.

Specialties and their Relation to the Medical Profession was the title of a paper by Dr. L. DUNCAN BULKLEY, of New York. The following were his conclusions: 1. The science and practice of medicine were so vast that it was beyond the power of one mind to grapple with them as a whole. 2. Divisions of study and practice had been made unconsciously. 3. So-called specialists were those who devoted exclusive attention to their branches. 4. By the development of these they increased the scope of medical knowledge. 5. Every one should be more or less a specialist, in that he should know or do some one thing better than others. 6. Specialists should have a thorough training in general medicine in addition to their special preparation. 7. Specialties would be limited by the law of supply and demand, and by the increased teaching of special branches in our medical schools.

The Report of the Standing Committee on Laws regulating the Practice of Medicine in the United States and Canada, read by Dr. DUNGLISON, showed that Virginia had been the only State to enact a medical law since the last meeting.

The president appointed Dr. L. Duncan Bulkley and Dr. E. H. M. Sell, of New York, additional members of the Council.

Votes of thanks were passed to Dr. Lee, the retiring president, and to the authorities of the Johns Hopkins University for their courtesies.

The Academy then adjourned, to meet in New York in 1885.

PHILADELPHIA CLINICAL SOCIETY.

Meeting of September 26, 1884.

Imperforate Anus with Recto-Vaginal Fistula in the Adult.—Dr. CLARA MARSHALL read a report of two cases, which she reserved for publication.

Atresia Vaginae with Retention of Menses.—A case was reported by Dr. E. E. MONTGOMERY. Miss F., aged forty-four, had been brought to him July 5, 1884, by Dr. Sibbald, of Wissahickon, with the following history: She commenced menstruating at sixteen, and continued without disturbance until her thirtieth year. Two years previously she had fallen upon a curbstone, receiving quite a serious spinal injury, from which she fully recovered in a year. The menstrual periods, which had always been regular, lasting from three to four days, normal in quantity and color, at thirty became painful. Since then the pains had been constant and had increased with each period.

The discharge now lasted from seven to ten days, and was of a dark color and offensive odor. During the menstrual intervals there was a continuous discharge of "corruption," as she called it, making the constant wearing of a napkin necessary, and producing excoriation. All of these symptoms had been increasing during the past eight years, and she had been compelled to discontinue work a week or more at a time. She complained of a sensation of weight or pressure in the pelvis, attended with severe pain during defecation. There was no pain during micturition. Her nervous system had become much affected. Upon examination, the vagina was found relaxed, and the external parts red and bathed with secretion. The vagina was about two inches long, ending above in a lateral cicatrix. No uterus could be felt. Upon withdrawing the finger, it was found bathed with a dark, thick, highly offensive discharge. The use of a Sims's speculum disclosed a cicatricial line running from side to side across the fundus of the sulcus, just posterior to which the membrane looked thinner. Slight pressure against this with a sound perforated it, and this was followed by a profuse discharge of broken-down blood and pus. Ellinger's dilator was then introduced and spread to its full extent; over four ounces of the fluid flowed out. The cavity was then washed out with a carbolized solution. In this cavity above the cicatrix the uterus was found retroverted and firmly fixed, forming the roof. The cavity was dressed with carbolized glycerin on cotton. The subsequent treatment was conducted by Dr. Sibbald. He had informed Dr. Montgomery that there had been no further difficulty.

Dr. W. H. PARISH thought that the treatment adopted in this case was proper, as the result showed, though it was not in accordance with the treatment directed by the text-books. We were there told to puncture the cavity with a trocar and draw off the confined liquid drop by drop. This was undoubtedly wrong, and its disadvantages had been demonstrated in his own practice. The crucial incision was unquestionably best.

Dr. COLLINS related the details of a case treated after the manner of the text-books, with an exploring needle, a trocar, and drop-by-drop drainage. The cartilaginous membrane acting as septum was an inch and a half from the vulva, and was probably congenital. A crucial incision was made after drainage, and the corners were cut off. No further trouble was experienced by the patient.

Dr. MONTGOMERY thought, with Dr. Parish, that a free incision was best, though it had been precipitated in the case related by an opening occurring during the examination. The danger of septicæmia was certainly increased by a small opening. A particular point of interest in this case was the lateness in life and the time that had elapsed between the injury and the retention.

G. BETTON MASSEY, M. D., *Reporting Secretary.*

BROOKLYN PATHOLOGICAL SOCIETY.

Meeting of October 9, 1884.

The President, Dr. B. F. WESTBROOK, in the chair;

Dr. A. H. P. LEUF, Secretary.

Enchondroma of the Finger.—Dr. HERBERT C. ROGERS related the case of an Irishwoman, sixty-five years old, who came to his clinic at the Long Island College Hospital January 6, 1883. Twenty years before, she had been knocked down by a stage, picked up insensible, and carried to the Chambers Street Hospital, where it was found she had sustained a fracture of the right hip. She remained in the hospital three months, when she was discharged, and had been compelled to use crutches ever since. She thought that at the time of the injury she hurt

her finger, for about six months afterward it began to swell at the junction of the first and second phalanges. The tumor gradually increased in size; at times it was the seat of sharp, shooting pains. Six months ago it broke and discharged a thin, watery pus mixed with blood. The fistula had never healed, and the discharge had persisted.

Examination of the finger showed a globular tumor of about the size of a pullet's egg, with a small fistulous tract on the upper side which led to necrotic bone. Dr. Rogers amputated the finger at the metacarpophalangeal junction, and the stump healed promptly.

Atheroma of the Aorta; Rupture; Granular Disease of the Kidneys.—Dr. J. D. SULLIVAN related the case of a lady, fifty-three years old, who had enjoyed good health up to about three years ago, at which time she had an attack of sickness which was said by her physician to be pneumonia. This illness continued for a considerable length of time, and her physicians finally despaired of her recovery. Her husband then discontinued all medical treatment, and had her removed to the country, where, by a system of forced diet, consisting largely of milk-punch, she gradually improved so that within the following six months her health was considered quite restored. Since that time she had been in pretty fair health, and had continued to take her alcoholic stimulants as part of her daily nourishment.

On February 18, 1884, at 7.30 p. m., Dr. Sullivan was hastily summoned to see her, as she had suddenly been taken seriously ill. Although he reached her residence in about twenty minutes, she died as he entered the room. He was then informed that for two or three days she had complained of a pain in the præcordial region, which produced a sensation of numbness along the left arm to the hand. She had just eaten a hearty dinner, during which she was quite cheerful. As she went up stairs after dinner she said the pain in her left breast had become more severe, her breathing became rapid and shallow, and, as the intensity of the pain increased, she began to cough up bloody mucus and experienced the utmost difficulty in breathing. This distressed condition continued about twenty minutes, when she died.

A post-mortem examination was made, fifteen hours after death, by Dr. J. H. Hunt, Dr. Alexander Hutchins and Dr. Sullivan being present. Rigor mortis was extreme; the body was well nourished. Hypostatic congestion was very marked over the entire left side and arm. There was a large amount of black blood in the left pleural cavity. The left lung was very oedematous, but otherwise healthy, with the exception of an old cicatrix at the apex. The right lung was adherent to the chest-wall, also very oedematous, with a cavity in the apex, which apparently had healed. There was no blood in the right pleural cavity. On the internal surface of the arch of the aorta there were numerous spots of atheromatous degeneration. These spots varied in size from that of a small speck to half an inch in diameter. At the commencement of the descending portion of the aorta, near the origin of the subclavian artery, there was an atheromatous patch of about the size of a half-dime, where the internal and middle coats were entirely destroyed, and the external coat was perforated. But the areolo-fibrous investment or sheath remained intact, so that, in passing a probe through the perforation, no opening could be found in the sheath of the aorta.

There was an atheromatous deposit of about the size of a silver ten-cent piece near the origin of the arteria innominata, which was attached at one border only, and allowed the opposite border to move to and fro like a valve. This deposit became detached while manipulating the specimen. The liver showed marked evidence of fatty degeneration. The gall-bladder contained twelve pretty large-sized calculi. Both kidneys

were in a state of granular degeneration. They were small, hard, and contracted, irregular in shape, in consequence of the shrinking having taken place unevenly, and the surface was studded with hemispherical granulations.

There were many points of interest in relation to these specimens, but the speaker would briefly allude to only a few of them. 1. There would appear to have been some connection between the perforation in the arch of the aorta, near the origin of the left subclavian artery, and the pain in the left side of the chest and left arm, which troubled the patient for several days before her death. It was difficult to say whether the pain had been produced by the progress of the disease in the coats of the aorta, or by the aneurysmal bulging of the external coat, and consequent pressure on the adjacent tissue, or whether the diseased spot caused some interruption to the normal flow of the blood-current. There were no adhesions nor any evidence of any inflammatory action in the surrounding tissues. 2. Judging by the symptoms, and the post-mortem condition of the lungs, it was evident that there was some great obstruction to the return of the blood from the lungs to the heart. For about fifteen or twenty minutes before death large quantities of frothy, bloody mucus were coughed up, and after death the lungs were found intensely congested and oedematous, and the bronchi filled with the same kind of bloody mucus. It was peculiar that there was considerable blood in the left pleural cavity, and yet no opening could be found through the sheath of the aorta or the pleura. It was probable that the blood had dissected its way between the aorta and its sheath for some distance before bursting into the pleura. 3. He would draw attention to the kidneys and one or two possible causes of their diseased condition.

It was quite probable that the patient's illness three years before, which continued for some months, and during which her physicians despaired of her recovery, was an attack of pleuro-pneumonia. Was it not safe to presume that the pathological condition then existing for a considerable length of time had acted as a cause in producing the disease of the kidneys? His observations and experience led him to believe that the morbid products of inflammation retained very long in any portion of the body imposed an additional task on the kidneys, and tended to excite disease of their structure. He mentioned this point, not that there was anything new or original in it, but because many of those who had written upon renal diseases had not even alluded to it as a cause of kidney degeneration, and because he had reason to believe that it was frequently either ignored or but lightly considered. In his opinion, it was a point worthy of more careful consideration. There was another element in the history of the case which might be considered as having had a causative influence not only in damaging the kidneys, but also in bearing upon the fatty degeneration of the liver and the atheromatous condition of the aorta. It was noted that during the last three years alcoholic drinks were taken, although in moderation, yet as a part of the patient's daily food. The alcohol might have served a good purpose in assisting in the restoration of her health when she was low and feeble, but its continued use had certainly been injurious. By interfering with nutrition, the continued use of alcohol, even in small quantities, would lead to deterioration of the various tissues of the body.

Dr. FERGUSON called attention to a marked myocarditis present in the specimen. It showed many spots of fibroid induration. Subjects in this condition might die suddenly without a rupture of a blood-vessel or an aneurysmal sac.

Dr. HUNT remarked that, while in this case blood was found in the left pleura, no complete opening could be discovered in the wall of the sac. The inner and middle coats had been rup-

tured, but the outer one was intact. He supposed that the blood had filtered through the adventitia and surrounding connective tissue, as they were infiltrated with blood.

Colloid Degeneration of the Thoracic and Abdominal Viscera and the Diaphragm; Death.—Dr. JOSEPHINE A. DUPRÉ related the following case:

An Englishman, fifty-five years old, a machinist, was admitted into St. Luke's Hospital, New York, February 14, 1881. He had always been a sober man, and had been healthy up to one year before. He then noticed for the first time that his urine was dark-colored and that his stools were clay-colored. At that time he began to suffer from backache and headache, and feel very dull and stupid, and was taken with a severe cramp in his right side, which prevented him from straightening himself out. The pain was principally located along the course of the ascending colon. After that, nausea and vomiting were prominent symptoms; for days he would vomit everything ingested. Since the cramp he had had a girdle of pain at the level of the epigastrium.

At the time of his admission he was extremely jaundiced. He had not noticed this until five months before. Before that he had disturbed vision, xanthopia, headache, ringing in his ears, and vertigo, and also felt dull and apathetic. He now felt very weak, had vertigo when standing, his appetite was fair, and he drank a large quantity of water. His bowels were loose; he had not vomited for two days. The specific gravity of the urine was 1.020; it was acid in reaction and dark-colored; chemical examination showed nothing abnormal. He had had chills and fever fifteen years before, lasting nine days, and again, six years before, lasting three months. He was vaccinated nineteen years before, and stated that, immediately after that, he was covered with an eruption, and that his hair afterward came out, and he had a sore throat. For two months before his admission his feet had been swollen and he had had considerable ascites. There had been no epistaxis or hæmatemesis. He had never had any venereal disease. From the time of his becoming jaundiced he had complained of itching, anorexia, flatulence, offensive clay-colored stools, headache, and insomnia.

Examination showed tenderness over the liver, which organ, together with the spleen and the heart, was displaced upward by flatus. There were no nodulations over the abdomen; the liver was decreased in size. There were some enlarged cervical and inguinal glands.

On the 24th he was still jaundiced, and had flatulence and headache. On the 27th he was suffering with nausea, vomiting, and hæmorrhoids.

On the 1st of March the urine was alkaline, and contained a quantity of bile and traces of albumin.

On the 2d he had fever in the afternoon, with vertigo.

On the 5th, dullness was found over both flanks. The liver reached to within an inch and a half of the umbilicus; there was tenderness over its lower border; and there seemed to be an irregular hard spot at the inner side of its right lobe. There was moderate tympanites, with ascites. The feet had been swollen for two weeks. He continued to have night-sweats.

On the 8th a diagnosis was made of malignant disease of the liver.

On the 14th it was noted that he had constant pain across his epigastrium, extending around toward the right to the small of his back. This was not affected by the condition of his bowels, or the ingestion of food. The spleen was not enlarged. His condition changed daily for better or worse. His temperature was elevated.

On the 30th he was more deeply jaundiced, and was losing flesh, but was free from pain. The specific gravity of the urine was 1.024; it was acid and contained granular matter and a

trace of blood, the bile being in less quantity than before. The jaundice and flatulence soon began to subside.

On the 4th of May it was noted that he was very weak, and that there was considerable ascites. The size of the liver and spleen could not be made out, on account of flatulence. The liver was enlarged; the lungs were normal.

On the 9th it was noted that he was losing flesh. There was no nausea or vomiting. There was oedema of the abdominal walls, he complained of cramps in the abdomen, the jaundice was increasing, he was very weak, and his temperature was elevated.

On the 18th there was feeble respiratory murmur all over the chest posteriorly, with a few moist râles at the base of the right lung posteriorly.

On the 21st the specific gravity of the urine was 1.022, and it contained amorphous matter, pigment particles, bile, and a trace of albumin, and was alkaline. At the level of the seventh rib, on expiration, the right side of the chest measured 17½ inches, and the left side 17¾ inches. His temperature had ranged between 99° and 101° F. during his illness.

From April 1st to April 25th he passed between seventy and fifty ounces of urine per diem, from April 26th to May 8th between fifty and thirty ounces, from May 9th to May 24th between forty and twenty ounces. He was discharged, unimproved, on the 24th.

The foregoing facts Dr. Dupré had obtained through the courtesy of her friend, Dr. C. Ellery Dennison, late house surgeon at St. Luke's.

The patient came under her care three days after leaving St. Luke's, and she undertook the case for the sole purpose of securing an autopsy as soon as death occurred, which happened on June 16th.

During the three weeks that he survived she sought to allay the gastric symptoms, relieve pain, secure rest, and supply nourishment. His condition differed in no essential manner from what it had been while he was in the hospital. Death was due to slow asthenia.

The autopsy was made by herself, assisted by Dr. E. M. Cushier, and Dr. E. J. Chapin, of New York, about fifteen hours after death. The body was extremely emaciated, and its surface deeply jaundiced, except at the lower part of the upper and lower extremities, which were very pallid, and enlarged from oedema. The ends of the fingers were clubbed. The conjunctivæ were jaundiced to an olive-green hue. The abdominal wall was tense and oedematous. The abdomen was greatly distended with fluid and flatus. A large quantity of dark-green fluid was removed from the abdomen. The intestines were greatly distended with flatus. The omentum had floated up under the diaphragm, and was so closely rolled upon itself as to give during life the impression of an enlarged and carcinomatous liver. When spread out, it presented a remarkably beautiful appearance. Its entire surface was freely studded with nodules, pale-pink, yellowish, or greenish hued, and varying in size from that of a pin's head to that of a small cherry. The free border for about three inches presented an aggregated mass of these bodies. Both the parietal and visceral layers of the peritonæum were dotted at irregular intervals with the same translucent, pale-yellow, or pinkish masses. In the right lumbar region the duodenum, the pyloric end of the stomach, the head and body of the pancreas, the hepatic flexure of the colon, and numerous lymphatic glands were all matted together as though glue had been poured out in this region. The peritoneal covering of the diaphragm was found studded with these "colloid" masses. The parietal pleura was found in a similar condition. The left lung was bound to the chest-walls by old pleuritic adhesions, which were with difficulty separated. All of the thoracic organs

were removed, and the investigation was continued March 10, 1884, with the assistance of Dr. A. H. P. Leuf, who had kindly prepared microscopic specimens which he would show at the meeting.

The liver was normal in size and consistence, except where this degeneration existed. Scattered throughout its substance could be seen these "colloid" masses, varying in size from that of a pin's head to an inch or more in diameter. The peritoneum covering the liver was very much thickened where it was in contact with these growths, and firmly adherent. A piece of the peritoneum attached to the fissure of the ductus venosus was studded with "colloid" bodies, varying in size from that of a pin's point to that of small peas. The cystic duct was occluded; the hepatic duct was normal: the round and broad ligaments were infiltrated and thickened with fine masses of "colloid" material.

The diaphragm was infiltrated and thickened throughout its entire extent with "colloid" material to such a degree as to appear like sole-leather. It was adherent to the upper and posterior part of the right lobe of the liver. The ductus communis choledochus was infiltrated with "colloid" matter as it entered the duodenum. The pancreatic duct was very much dilated. The substance of the pancreas was also infiltrated with "colloid" material. The middle portion of the pancreas had undergone cystic degeneration. The head of the organ was converted into a mass of "colloid" substance.

The spleen was not enlarged; its surface was studded with particles of "colloid." There was also "colloid" material in the hilum of the spleen. There were no nodules in its substance.

Portions of the parietal peritoneum showed particles and patches of this "colloid" matter, some of which were firmly adherent, while other parts were easily detached.

The greater omentum was one mass of "colloid" bodies of different size. The free border formed a thickened margin by the aggregation of these nodules an inch or more in width and half an inch in thickness. The lesser omentum presented about the same appearance as the greater.

The transverse colon was normal. The interior of the stomach was normal. Its pyloric orifice was infiltrated with "colloid" material. The ascending transverse and descending portions of the duodenum had undergone "colloid" degeneration, and the "colloid" matter projected into the cavity of the duodenum in the form of fungous growths. The muscular and mucous coats were entirely destroyed by this degeneration. The lymph-glands at the lesser curvature of the stomach were so much enlarged as to measure, collectively, six inches in diameter.

The heart was normal, except a peculiar open or lace-work appearance along the margins of the aortic and pulmonary valves, and a large post-mortem clot in the right auricle.

The substance of the right lung was infiltrated with "colloid" matter. The posterior surface of the anterior edge of the upper lobe of the right lung had a patch of "colloid" material about eight lines in diameter, adherent to the pleural covering, but it was easily detached. The free surface of the patch was rough, as though it had been adherent to the parietal layer of the pleura. The left lung was also infiltrated with "colloid." Between the lobes of the left lung there was an enormous gland.

The pleura over both lungs was freely studded with patches of this "colloid" material in varying stages of formation or degeneration. Otherwise, the lungs were normal.

The bronchial glands were very much enlarged, varying in diameter from an inch to an inch and a half. Some of these glands showed a honey-combed appearance in structure.

Dr. A. H. P. LEUF said that, at the request of Dr. Dupré, he had made a number of sections from clumps of colloid material taken from the viscera in this case. These collections were distinguished by being circumscribed nodules, as could be seen with the unaided eye, but the microscope revealed a continuation of this discrete arrangement in detail. Every clump, or part of a clump, that was examined minutely was seen to consist of round or oval collections of many concentric layers of a comparatively firm and transparent substance. Inclosed within these were to be observed large and small cells, having a slightly granular protoplasm and one or more nuclei. They were mostly found well in the center of each round or oval mass, but others were also to be noticed between the layers nearer the periphery. These masses, consisting of so many concentric layers, were separated from one another by bands of connective tissue, or, in other words, they rested in alveoli, or cells like those of the honeycomb, formed of connective tissue. In several of these specimens it would be noticed that the transparent gelatinous substance forming the concentric layers had disappeared and left but a few whole and broken cells behind in the connective-tissue alveoli. On account of the thickness of these sections, which they usually had to have to be well studied, it would be necessary to keep changing the focus of the microscope while looking at the object so as to bring into view different layers of the section, and in that way demonstrate more clearly the concentric arrangement of the laminae of these little masses.

Colloid changes were at one time believed to be a certain variety of carcinoma, and by that he meant that colloid was formerly supposed to have had its characteristics from the beginning. It was now, however, more generally thought to be a degenerative change of an epitheliomatous growth, and yet it was difficult to find the gradations that one must expect to find under such an hypothesis. In all the sections made from various viscera of the specimens shown this evening, there was the remarkable sameness that would now be seen in the slides. The interesting fact to be noted in the microscopic details of this case was the comparatively large number of cells among the colloid matter.

Dr. FERGUSON remarked that in cases of colloid degeneration in the male it was exceptional to find the testicles not involved.

Dr. HUNT asked if the pancreas might not have been primarily affected in this case, as it was so extensively degenerated.

Dr. FERGUSON thought not, because the disease almost invariably began in the stomach, or ovaries, or testicles, on account of the abundance of epithelium in these organs, but the pancreas was often secondarily involved. He asked if the pylorus had been much affected.

Dr. DUPRÉ answered that the pylorus had been but very slightly affected, while the pancreas had been almost entirely replaced with the colloid material, and it was this that seemed to her to indicate that the latter organ was the primary seat of the disease.

Dr. FERGUSON said he did not deny the possibility of the degeneration having primarily affected the pancreas, but, if it had, it was a rare case in that respect.

Dr. LEUF called attention to a point that had not been brought out. This case showed very clearly how the colloid degeneration might extend by contiguity of structure. A nodular mass of colloid material measuring fully 3 cm. in diameter was found located in the diaphragm and extending upward into the base of the right lung and downward into the right lobe of the liver. About one half of it was lodged in the liver, and appeared to have originated in this organ. There were many such illustrations in this case.

(To be concluded.)

MEDICAL SOCIETY OF NEW HAVEN COUNTY, CONNECTICUT.

Semi-annual Meeting, held at the Elliott House, New Haven, Thursday, October 23, 1884.

The President, Dr. R. B. GOODYEAR, of North Haven, in the chair.

Election of New Members.—The following-named gentlemen were elected members of the society, having been recommended by the Committee on Credentials: WILLIAM R. MARSDEN, M. D., University of the City of New York, 1881, of Meriden; THOMAS L. AXTELL, M. D., University of the City of New York, 1880, of Waterbury; JAMES L. TERRY, M. D., College of Physicians and Surgeons, New York city, of Meriden; JOSEPH W. JEWETT, M. D., University of the City of New York, 1881, of New Haven; and LEONIDAS C. FINAL, M. D., Yale College, 1880, of Branford.

Sanitary Training in Public Schools.—Dr. A. W. LEIGHTON, of the Committee on Hygiene, read a paper on this subject, of which the following is an abstract:

At present our system of education, like many other existing institutions, was being made the subject of no little criticism. Its imperfections were being pointed out and desirable alterations were being suggested. It was evident that hitherto practical training had been made subordinate to the ornamental branches. In the improved curriculum what place should be occupied by sanitary knowledge? Such training must necessarily be elementary, but should nevertheless be comprehensive. Instruction should not be limited to physiology and personal hygiene, but should be extended so as to include public hygiene as well. This training should be introduced not only into institutions of advanced learning, but also into the graded schools where boys and girls are being taught, who, at the age of thirteen or fourteen, must begin a life of independence, and come daily under the laws of life of which they were now so ignorant. Through lack of training of this kind parents exposed their children to illness, and themselves to bereavement and pecuniary loss, because they failed to recognize the laws governing the transmission of communicable disease. Individuals brought upon themselves transient inconvenience or permanent disability by exposure, overwork, and innumerable other hygienic sins, whose import they did not realize. No one could compute the suffering, the wrecked lives, the immediate and remote disaster, the countless consequences of ignorance and disobedience of hygienic law, as applied to the individual and his or her offspring. But where and how should such teaching begin? Where should this helpful knowledge be inculcated? The home and the street were important educational factors, but we could not rely upon contact with parents in-doors and upon the social atmosphere outside for intelligence in health matters; for, although the children owed much of their practical knowledge of life to these sources, they were also sources of prejudice and superstition. These influences were responsible for many injurious personal habits, for the maintenance of quackery, for the ridiculous and harmful therapeutic folk-lore, for the dogma that death and disease were dispensed for moral purposes. Nor could we expect sanitary instruction from periodical literature or from the daily press—that educator for which so much had been claimed and from which too little that was true and elevating proceeded. This training should stand second to none in any system of elementary education, and in some form should be considered essential in every department of liberal or professional study. Many improvements had already been made in the teaching of children in the primary schools, but an examination of the whole scope of public instruction revealed inconsistencies that would

not always be tolerated, and the most profound inconsistency of all was this: the teaching of everything and anything but the most necessary and elementary knowledge of the preservation of life and health. The public-school course comprised an imposing series of studies. And yet the conspicuous absence of all health instruction from the grammar-school course, taken with the fact that the great majority of boys and girls could have no further school preparation for life, would lead one to infer that such beings were mere automatons to be fitted only for business, stored with the conventional accomplishments of polite society, and utterly independent of the laws of individual or general life and health. In the higher institutions of learning, also, the instruction on this subject, was incomplete and inadequate. But it was only in the public schools that direction could be given to the main stream of youthful life as it flowed out beyond the sources of systematic education. Those who were familiar with people whose circumstances forced them into industrial occupations and the active struggle of life at an early age knew what a slight chance there was in after years for acquiring the essential knowledge for which we contended.

Believing that some elementary instruction in sanitary science in the grammar schools was both feasible and advisable, it was suggested that the following addition be made to the course, if necessary, at the expense of the least important studies. To begin the experiment, a weekly conversation on this subject should be held in one of the schools, the scholars of the two highest rooms being divided into two classes according to sex, and the exercises being conducted by a physician or other person especially adapted to the work. In these talks mental confusion from multiplicity of details should be avoided. At first, simply the essential principles of sanitary science, including personal hygiene, should be set forth. First of all, the youth should be taught to give this subject conscientious thought, and then helped to knowledge appropriate to their age and mental capacity. All average boys or girls of fourteen years should know what clothing was best for them, and what and when to eat. They should know the penalties that followed heavy lifting and straining, the compression of the chest and abdomen, and the exposure of the feet and extremities to climatic influences. They should know the chief dangers of resorting to nostrums of unknown composition for maladies of the nature of which they knew nothing. They should know what the death-rate was and why it varied, the function of quarantine, the essentials of house drainage, heating, and ventilation, and the chief results to be gained by the cleaning of cities, the avoidance of soil-pollution, and the pollution of drinking-water. They should have an idea of what worry was and the effects of it, and of mental and physical work without sufficient relaxation. They should know the hygienic as well as the moral bearing of vice and intemperance, and that they were immoral chiefly because they were injurious. Especially should the laws of heredity be taught, and their applications, so far as known, to those diseases and traits which were most baneful.

Thus through elementary training might valuable results be hoped for. These children would be taught to be thoughtful and observing, and they would be dismissed well furnished with the material to continue these studies, and prepared to exert a favorable influence on public sentiment in regard to sanitary questions.

An Electric Laryngoscope.—Dr. M. C. WHITE said that for a long time he had been anxious to obtain a better light for microscopical work. The construction of electric lights had led him to hope for something better from this direction. Last winter, at a meeting of the Royal Microscopical Society in London, a small lamp for use with the microscope had been shown. Recently, at the Electrical Exhibition at Philadelphia, a lately

patented instrument, designed for the use of dentists and surgeons in examinations of the mouth and throat, had been exhibited. Such an instrument Dr. White had prepared to show the society. It consisted of a laryngeal mirror, the shank of which had been replaced by an incomplete cylinder in which was a small incandescent lamp. This incensement was of hard rubber, so that no unpleasant degree of heat would be communicated to the mouth. The lamp was arranged near the mirror, so that it was kept warm and the rapid condensation of moisture upon it prevented. It was also so placed that a clear white light was reflected from the mirror, showing the real color of the tissues. The handle of the instrument contained a resistance coil, so as to diminish, and otherwise regulate, the intensity of the current. Four Bunsen cells of good size were connected with the instrument. At the hospital fifteen Leclanché cells were used to produce the same amount of illumination. It was probable that this instrument would be rapidly introduced into surgical practice. It was said to have been already used to illuminate the stomach.

Monstrosity with Deficient Cranial Development.—Dr. FRANK E. BECKWITH, of New Haven, presented a premature still-born fetus which had been carried nearly to full term. There was a large hernia of the brain, due to greatly deficient development of the occipital bones. This fetus had presented by the breech. Statistics showed that the head presented in 98 per cent. of deliveries at term, but in only 83 per cent. of premature deliveries. The breech presented in one of sixty cases of delivery at term, but in one of from two to six cases of premature delivery. The center of flotation was altered by the death of the fetus, so that the proportion of breech presentations was increased to one in three or four of this class of cases.

The Prognosis and Treatment of Scarlatina was the subject adopted at the last meeting for discussion at this time. Dr. M. C. O'CONNOR, of New Haven, chairman of the committee to report upon the question, read an elaborate review of the teachings of various authorities upon the subject. A summary of the more important conclusions deduced is as follows:

There was scarcely a disease in which the element of uncertainty entered so largely as in scarlet fever. The various types, forms, and complications, as well as the epidemic influence prevailing at the time, had great influence in determining the tendency toward death or recovery. The mortality was greatest in infants and in children under five years. In the puerperal state it was almost invariably fatal. Flint stated that he did not know of an instance of recovery. Occurring during pregnancy, it almost certainly ended in abortion.

In the prognosis of individual cases caution was necessary. Apparently mild cases were not free from the danger of severe complications and sequela. Unusual malignancy of the disease might cause intense prostration, coma, and an early fatal termination. High initial fever, severe throat affection, and great depression indicated danger. Convulsions, especially occurring early, were of unfavorable import. Laryngitis usually proved a fatal complication. Very severe inflammation of the fauces, extending to the neighboring glands and connective tissue, rendered recovery doubtful. Gangrene of the mouth and hemorrhages from the mucous surfaces were also of grave import. The same was true of cardiac affections. Renal complications involved great danger. They should be anticipated by daily examinations of the urine. Even after the albumin had disappeared the patient was not safe if casts continued. Slight delirium at night in mild cases was not a serious symptom, but, if active and constant, more grave. The rheumatoid condition of the joints, frequently noticed, was rarely serious. A scrofulous constitution predisposed to glandular complications. An early favorable prognosis was to be avoided. Some patients died

after the fever had left them, from the anæmia produced by the fever. Sudden and unexpected deaths sometimes occurred from uræmia, but were more frequently due to the formation of ante-mortem heart-clots.

Scarlet fever could not be shortened or aborted by treatment. Mild cases did not require active treatment, confinement to the bed being sufficient, with milk diet and attention to the bowels, the application of some mild liniment, such as camphorated oil, to the neck, and a chlorate-of-potassium mixture for the throat. Severe cases required more heroic measures. Hyperpyrexia might be effectively combated by the external application of cold water. This would diminish the heat of the body and the frequency of the heart's action. Sleeplessness, restlessness, and delirium were also relieved thereby. Quinine might be employed for the same purpose, given in five-grain doses three times a day to children of five years. Aconite and veratrum viride were less suitable on account of their depressing effect. Digitalis was better, but inferior to quinine.

Itching of the skin and great restlessness, due to irritation of the peripheral nerves, might be relieved by inunctions with olive-oil, bacon-rind, cocoa-butter, and similar preparations, more effectually than by tepid sponging. Five or six drops of carbolic acid might be added to each ounce of fatty matter or of vaseline.

A tendency to prostration could be avoided, and the strength of the patient sustained, in severe cases, by alcoholic stimulants. Wine—either port, sherry, or Madeira—was usually preferable for children, administered in small quantities with water, arrow-root, jellies, or other light nutriment.

If the throat was severely affected, the swallowing of lumps of ice was grateful to the patient. In some cases the inhalation of hot steam seemed to give more relief. Chlorate of potassium was now generally considered an important remedy. From half a drachm to two drachms might be given in divided doses during twenty-four hours. Tincture of the chloride of iron was a useful addition. Chlorine-water was highly recommended by Watson and others.

Local applications were useful if properly applied. Little difficulty would be found in making the applications if a long wire-handled camel's-hair throat-brush was used to paint over the affected parts, and if promiscuous swabbing, which was not beneficial, was avoided. The mixture containing carbolic acid, solution of the subsulphate of iron, and glycerin, recommended by Professor J. Lewis Smith, acted most satisfactorily. This also answered well when there was a sloughy condition of the fauces. The spray was more difficult to use in these cases than the brush. Gum guaiacum had been used in scarlatinal sore throat, but without any marked benefit.

If there was much implication of the Schneiderian membrane, the above-mentioned mixture might be diluted, and syringed into the nostrils. This would prevent decomposition, remove the offensive odor, and guard against blood-poisoning. Carbolic acid and water (1 in 200) might be used for the same purpose.

Swelling of the neck should be met in the early stages with cold compresses, which after a day or two, if the throat was not benefited, could be exchanged for warm applications, as of spongiopilin dipped in hot water, or light, hot linseed-meal poultices frequently renewed. If there was any tendency to suppuration, the pus should be evacuated as soon as it could be detected, so as to prevent purulent infiltration of the tissues of the neck.

The painful condition of the ear could generally be relieved by dropping a little laudanum and sweet oil or glycerin into the ear, and the application over the ear of a poultice of steamed hops frequently renewed. If otorrhœa occurred, the ear should be syringed with hot carbolized water.

Convulsions should be controlled, as far as possible, by the inhalation of chloroform and the application of cold to the head. The action of the kidneys should also be carefully watched.

Uraemic phenomena required prompt attention. A saline purgative or the compound jalap-powder was to be employed to eliminate urea. Fomentations over the loins and dry cups should be used. Diaphoresis should be produced by hot-air baths or by pilocarpine. If the urine was scanty, mild non-stimulating diuretics should be administered—such as the salines and digitalis, the diuretic *par excellence*. In the mean time the strength of the patient should be supported by light but nutritious diet, and a liberal allowance of wine. Extensive anasarca required the use of cathartics and diuretics. In less acute cases of albuminuria, or where the albumin was gradually disappearing from the urine, the tincture of the chloride of iron produced a very excellent effect.

Restlessness might be relieved by cold applications to the head, warm mustard foot-baths, and the bromide of potassium. If these measures did not produce quiet and sleep, anodyne remedies, such as belladonna or hyoscyamus, might be required. If these failed, opiates could be given, but they should be used with great caution, particularly in children, or if uræmia threatened.

Nausea and vomiting could generally be relieved by the sucking of small pieces of ice, or by the use of cold carbonated water.

Rheumatic complications were best treated by saline laxatives and diuretics, while severe pain was relieved by anodynes. Salicylate of sodium had not proved beneficial, and was likely to increase the irritation of the kidneys if they were at all affected.

Constipation should be relieved by simple enemata rather than by cathartics, unless there were other indications for the use of the latter.

In malignant cases all measures frequently proved unavailing. Cold affusion was most useful in the ataxic form of the disease. Alcoholic stimulants must be used at the same time. Carbonate of ammonium and mustard-baths might also be employed.

During convalescence, exposure to cold must be guarded against, and iron and other tonics should be administered internally. During this period scrubbings with carbolic soap, or detergent baths with carbolic innunction, should be practiced for the purpose of disinfection. The New York Health Board advised the disinfection of clothing, etc., with a solution of sulphate of zinc and carbolic acid.

The weight of evidence was opposed to the belief that belladonna had any prophylactic value against this disease. It might be given in the form of the extract dissolved in cinnamon-water, with the addition of a few drops of alcohol to prevent fermentation.

Dr. C. A. LINDSLEY, of New Haven, remarked that he saw no good reason for continuing to use carbolic acid, in the strength hitherto commonly recommended, as a disinfectant. Experiments had shown, and the opinion was growing, that it was less valuable than other agents. A solution of sulphate of zinc and salt was now most used. It had the advantage of not being disagreeable. At present there was a growing feeling that corrosive sublimate was the best disinfectant. It was commonly used in the strength of one to one or two thousand parts of water, with the addition of ammonia, or salt, or an aniline preparation, so as to avoid the danger of mistakes from taking it internally. In New Orleans it was used exclusively for washing vessels, in addition to disinfection by burning sulphur.

Dr. S. G. HUBBARD, of New Haven, said that he had no belief in the prophylactic value of belladonna in preventing the communication of scarlet fever. Twenty years ago, in connection with Dr. Tyler, he had tried it. They gave a preparation,

similar to the one mentioned, to adults and children in infected families. The epidemic was a mild and pretty general one. They concluded that the occurrence or non-occurrence of the disease in persons who were taking belladonna was merely a coincidence. Both were of the opinion that no dependence was to be placed on it, or on anything, except, perhaps, fresh air in motion and fumigation of all fabrics in the sick-room. In some cases the disease was carried by clothing which had not been worn by the patient, but had been hanging in his room. Carpets and bedding, also, frequently did not receive the necessary attention. Cases were sometimes spread from a house a month or more after the patient had become convalescent. More than thirty years ago he made a similar set of observations in regard to belladonna. Now he knew of no one, except, perhaps, our homeopathic friends, who had any faith in its prophylactic influence. The eruption of the skin and the affection of the throat produced by the drug were entirely different from the manifestations of scarlet fever. It was stretching the imagination too far to believe that, because belladonna caused an eruption upon the skin and an affection of the throat, therefore it would prevent the disease.

Dr. M. N. CHAMBERLAIN, of Cheshire, reported that he had used sulpho-carbolate of sodium to a limited extent as a prophylactic against the disease with apparently favorable results. The number of cases, however, was not great.

Dr. LEWIS BARNES, of Oxford, believed that very little treatment was necessary. He sometimes gave chlorate of potassium, and had the patients bathed so as to keep the pores of the skin open and allow of the elimination of the poison. He had lost only one case—in a syphilitic subject.

Dr. W. R. BARTLETT, of New Haven, had used both carbolic acid and corrosive sublimate in medical and surgical practice, but was not prepared to give up the former, on account of the poisonous qualities of the latter.

Dr. WHITE expressed surprise at the statement that the disease did not need treatment. It needed treatment just as much as any disease. It was due to a poison in the blood, which could be destroyed before it got into the body, and why not also in the body? Prophylaxis should be the same as the treatment of the disease. Iron and potash were good for the sick, and therefore also for the well who had been exposed to the contagion. By the use of these remedies the severity of the disease was lessened and its progress cut short.

Dr. BECKWITH commented upon the unfavorable prognosis which had been given in puerperal cases, and reported three cases of moderate severity—not mild cases—which he had observed in puerperal women. Each had recovered without kidney or other complications. The disease bred its own kind, and the symptoms should never be interpreted as a septicæmia with a rash.

Dr. Hubbard's summary agreed with his own experience. Belladonna was worthless as a prophylactic. When patients asked him about it, he told them that belladonna should by no means be taken. It was impossible for such a drug to prevent the disease. Experiments in English hospitals had shown that it was ineffective.

It was dangerous to apply poultices and sedatives to the ear. If there was pain in the ear, the physician ought to examine it, or send for an aurist at once. Many persons were deaf from scarlatina. The time had come to examine the ears if they were painful. Many cases could be relieved by incision of the drum.

It was his custom to dress the patient in a flannel garment reaching from the neck to below the feet. By this means, in many cases, renal complications might be avoided. Otherwise it was impossible to keep children covered at night.

In order to limit the occurrence of the disease it was desira-

ble to keep the patients quarantined until desquamation ceased. Three to six, or, better, five to six, weeks should be allowed for this, before they were permitted to go to school or associate with other children.

If there was high temperature or twitching of the limbs, with a tendency to convulsions, the wet pack was the most desirable method of treatment.

Dr. W. O. AYRES, of New Haven, said that it had always been his practice to visit his scarlet-fever patients in the morning, and never to visit other patients, or go home, for at least an hour. By following this plan he had never had reason to suppose that he had carried the disease to his own or other children, although he had attended many cases during severe epidemics. In spite of all his precautions during the prevalence of the disease, at a later time, when he was not aware that there was a case of the disease in the city (San Francisco), his daughter was suddenly taken with it. He could not trace the source of infection. It was an instance of the terrible uncertainty which characterized the disease. He had no confidence in belladonna or any other drug as a prophylactic. The only thing was an abundance of fresh air and absolute disinfection thereby.

He always advised the avoidance of cold water for from six to ten days after the termination of the febrile stage, while the skin was sensitive. He had seen very few of the severe complications, and believed it was due to the avoiding of cold.

Dr. W. H. CARMALT, of New Haven, spoke in regard to the ear complications. He considered the application of remedies to the external ear as worse than useless, as time thrown away. The condition was an acute middle-ear catarrh extending from the throat. For temporary relief of pain, hot applications were useful, but the ordinary mode of application was non-effective. A large poultice to the external ear did no good. The proper way was to fill the ear with hot water, and then to lay on hot cloths. This was a purely temporary means of relief, and should only be resorted to for a few hours. The only remedy was incision of the drum-membrane, and that should be done early.

An effort should be made to prevent the starting of suppuration. This was too much neglected by physicians. The throat and posterior nares ought to be cleansed thoroughly—not by a gargle, or by the finger dipped in alum—but with a probang covered with cotton introduced into the throat. This was difficult to do, and frequently it was necessary to use some force. But, if we expected to do any good, we must do it in that way. Physicians told their patients that they would grow out of the deafness. But, even when seen five, ten, or twenty years after the occurrence of the disease, they had not grown out of it; they had grown worse. The nasal douche, if used carefully by the physician, was very useful, but, used by the patient, very dangerous. It might excite suppurative inflammation of the ear, and two cases of death had been reported following its use. Warm, medicated water snuffed up into the nostrils through a small rubber tube was useful, and there was little, if any, danger of any fluid entering the Eustachian tube.

Dr. H. FLEISCHNER, of New Haven, stated that sometimes he had voluntarily endeavored to communicate the disease to children during a mild epidemic, and last spring, during a severe epidemic, used no care in regard to transporting the disease. He had failed to communicate it to any one. He believed that antizymotics, germicides, and antipyretics were of no use. Mild cases needed no treatment. In severe cases he treated symptoms and relieved restlessness with chloral, pains with opium, and cardiac failure with brandy.

Dr. BECKWITH protested against following Dr. Fleischner's example. Every precaution ought always to be taken to avoid carrying the disease to healthy children. He always endeavored

to see his scarlatina patients last, and not to go immediately to other patients from cases of scarlatina of any grade.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Wednesday's Proceedings.

The Care of the Eyes in School-Children was the subject of a paper by Dr. STEPHEN O. RICHEY, of Washington, which, in the absence of the author, was read by the President. The author called attention to the gradual increase of myopia in this country, and compared the improper use of the eyes to dissipation. It had been found that the proportion of children affected with myopia was greater in the higher classes at schools than in the lower classes. Among the causes of the evil enumerated were too prolonged use of the eyes, with a poor light and a bad posture of the scholar, and the fact that slight errors of refraction were overlooked, instead of being remedied before they became pronounced. Progressive myopia could easily be avoided, and the eyes of school-children should be examined every six months. The use of pen and paper should be substituted for that of the slate and pencil, but particular stress was laid upon the strain of reading the same kind of print for several hours in succession.

Cotton-seed Oil as Food was the subject of a paper by Professor CHARLES E. MONROE, of Annapolis, who called attention to the importance of investigating the qualities of this oil as a food, inasmuch as it was in extensive use under the name of olive-oil.

The Sanitary Survey of the School-houses of Indiana was the title of a paper by Dr. E. S. ELDER, secretary of the board of health of that State. In spite of the pride felt by the people of Indiana in their school system, the reader said, there were many defects in the construction of the school-houses, and in other respects, a number of which he pointed out. It was certain, however, that improvement was going on in these matters.

The discussion on school hygiene was opened by Dr. RAYMOND, of Brooklyn, who said that too much attention was paid to the public schools in comparison with what was paid to the private schools. When private houses were used for school purposes, the occurrence of infectious diseases in the family was too apt to be kept secret. The same thing was true of public schools where the janitor's family lived in the building. Nobody ought to live in buildings devoted to school purposes. In Brooklyn, no pupil who had recovered from an attack of infectious disease was allowed to return to school without a permit from the sanitary officials.

The subject was further discussed by Mr. BROOKS, of New York, Dr. THOMPSON, of Kentucky, Dr. REED, of Ohio, the President, Dr. BRYCE, of Toronto, Dr. A. N. BELL, of New York, Mr. L. A. SMITH, of Washington, Dr. G. F. CONN, of Concord, N. H., Dr. WILLIAM BAILEY, of Louisville, Dr. EARLY, of Indiana, Dr. FEE, of Kansas City, Dr. DEVRON, of New Orleans, Dr. GREENE, of Pennsylvania, and Dr. J. F. HIBBARD, of Richmond, Ind. Dr. Fee protested against much that had been said in criticism of the methods pursued in the management of schools, and particularly of the way in which the teachers took care of the children committed to their charge. So far as his own State was concerned, there was not a teacher in St. Louis, or in the whole of Missouri, that did not know better than to teach a child in the first or second grade from written or printed copies, nor one that did not have a good idea of hygiene; and he ridiculed the charge that so much myopia was due to the neglect of the hygiene of the eyes in schools.

Poisonous Cheese.—The subject of cheese poisoning was

dealt with in a paper by Professor V. C. VAUGHAN, of Michigan, who had come to the following conclusions: 1. The toxic material in poisonous cheese is a chemical compound soluble in alcohol. 2. Its production is due to the rapid growth of the *Bacillus subtilis*. 3. The difference between poisonous and non-poisonous new cheese is one of degree rather than of kind.

The Milk Supply of Large Cities was the subject of a paper by Dr. J. C. MORRIS, of Philadelphia. He traced most of the mortality from diarrhœal diseases among infants to the use of adulterated milk. The shipment of milk in small glass jars was advocated, in preference to the use of the forty-gallon receptacles, with the indescribable filth that settled to their bottom, now so largely in use.

A Report on Cholera was received from the National Conference of State Boards of Health, the point of which was, that the general Government should be charged with the work of guarding against the invasion of the country by the disease, and that it should maintain a quarantine service at all the ports of the country, together with a system of warning by telegraph of the departures of vessels likely to be infected.

In the discussion which followed, the principle of quarantine was generally supported, and Mr. Brooks contrasted the system in use with us with the quarantines of Europe. The latter, he said, were brutal, cold-blooded, unnatural, and unnecessary, whereas our own system was merely the proper care of persons and goods that might possibly be infected. He moved that the report be printed and sent to the various officers of the Government. Carried.

The Investigation of Disinfectants, Antiseptics, and Germicides, by the association, for the purpose of disseminating knowledge with regard to these substances among the medical profession and the public, was the object of a series of resolutions introduced by Dr. HIBBARD, of Indiana. The resolutions were referred to the Executive Committee.

The Work accomplished by State Boards of Health was then made the subject of verbal reports by representatives of several of the boards, the general purport of which was that much was being accomplished, and that public sanitary work was sustained and appreciated by the people of the several States.

The Food we eat, the Liquids we drink, and the Adulterations we submit to was the title of an address by the Hon. ERASTUS BROOKS, of New York. After some general remarks on the constituents of the staple articles of food, and on the circumstances that affected it as contributing to the satisfactory nutrition of the body, Mr. Brooks proceeded to the subject of adulterations. The extent of food adulteration was one of the worst signs of the times. No country was free from this public evil, and it was next to impossible to reach and punish these abuses. Coffee had been adulterated until in some instances there was not an ounce of coffee to the pound, and three fourths of the teas sold were impure. Milk was adulterated in many ways, some of which were very injurious, and spices were well known to be largely adulterated. The adulteration of drugs demanded the attention of health authorities. In spirits, especially in wines, the adulterations were much worse than in coffee or general articles of food, and, in 1881, 56 per cent. of 3,861 samples of wine examined were found bad, and 6 per cent. dangerous. Butter should come from the dairy and not from the fat of animals. Glucose might be harmless enough, but, when 35 and 50 per cent. were mixed with honey and maple sugar, the deception was palpable and flagrant. Most kinds of oil were more or less adulterated, and the chief fraud consisted in calling oils by wrong names. Cheese was adulterated with potatoes or bean-meal, and the rind at times contained blue vitriol and arsenic to give it the appearance of age. Other

poisons were used to give the cheese a biting flavor, andlard-cheese was made at twenty-three factories in New York.

The Hygiene of Sailors engaged in the Coasting Trade was the subject of a paper by Dr. WALKER WYMAN, of the Marine-Hospital Service. Special reference was made to the hardships undergone by the oystermen of Chesapeake Bay.

Cremation as a Safeguard against Epidemics was the title of a paper by the Rev. JOHN D. BOUGLESS, of the navy. How, he asked, should we dispose of epidemics? Various means had been suggested. Epidemics, however, still came. No cordon of soldiers, no quarantine, could save us from epidemic, which came by usual and unusual channels. It came on the wings of the wind and walked in darkness. When it came, could we hope to drive it out by sending out quarantine vessels armed with chlorine, coppers, and acids? We might as well pour upon it the spray of sweet violets. Should we fumigate? We might as well burn sweet words. Disinfectants often turned out to be boomerangs, more dangerous than the disease. Whether microbes were the cause of the diseases of the zymotic type or not, they were always present, and certain microbes always produced certain diseases. Disinfectants, freezing, drowning, burying, and desiccating would not destroy any but the feeble microbes. Moisture and warmth seemed to be necessary to their sustenance, and our system of burial furnishes immense magazines of these microbes to the earth. These existed for hundreds of years, and in Medina an epidemic had been caused by digging up the bodies of those who had died of the epidemic three hundred years before. No disease germ could pass through the crematory fire and live to propagate its kind. Cremation was the only true germicide. Pope Clement V escaped contagion by building a wall of fire around his palace. Thirty-three per cent. of our deaths were caused by zymotic diseases, which could be obviated only by cremation. Instead, then, of laying our beloved dead into the cold bosom of earth, let us incinerate them and thus return them to the original ashes from which they rose. Potters' fields were a disgrace to civilization and a pest to the community. Let crematories be established in connection with all public institutions, and let this influential body memorialize Congress for this purpose. But this was not enough. All garbage, all sewage of the cities should be cremated.

The Ultimate Sanitation by Fire was the title of another paper, in the same strain, by the Hon. J. M. KEATING, of Memphis. A general discussion on cremation followed, in which the speakers were about equally divided as to its merits as a preventive of the spread of infection, but no new arguments were advanced.

(To be continued.)

Miscellany.

THERAPEUTICAL NOTES.

Hypodermic Injections of Phenic Acid in the Treatment of Inter-mittent Fever.—According to the "Union médicale," M. Dieulafoy lately reported at one of the meetings of a medical society a case of intermittent fever in which quinine had been given to the extent of 33 grammes in the course of two weeks before any impression was made upon the fever. The disease afterward recurred, and M. Dieulafoy began a series of subcutaneous injections of phenic acid, 2-5 centigrammes of a 1-to-100 solution being inserted night and morning for thirteen days, when the fever was arrested. The treatment was continued for three days longer, and the patient was then discharged cured. In the discussion, most of the speakers were inclined to regard the epi-

dence as conclusive in favor of the use of the remedy in malarial disease, but one of them stated that he placed much dependence on large doses of bromide of potassium after quinine and arsenic had failed.

Phosphorated Peptone for the Vomiting of Pregnancy.—In the same journal M. Judet speaks highly of this preparation, particularly in cases where there is a strumous diathesis. He maintains not only that it is a real aliment to the mother, but that it assists the assimilation of albuminoids, and hence furnishes to the fetus the proteids necessary for its development. He reports a case of obstinate vomiting in the third month of pregnancy, in which all the ordinary remedies had been tried in vain. Large doses of phosphorated peptone (6 to 12 tablespoonfuls daily) were given, all other nourishment being withheld, and in five days liquid diet was resumed. There was no further vomiting, and the patient not only made a good recovery, but nursed a large and healthy infant, although she had not been able to nurse either of her two other children. The peptone was continued in small doses throughout the pregnancy and until the end of lactation. The writer does not pretend to offer any theory as to the action of the remedy, nor does he appear to regard it as a specific; it is simply an aliment, especially to the osseous system, and probably exercises a sort of general tonic effect.

Portable Antiseptic.—"Professor Lister," says the "British Medical Journal," "has recently recommended, as a portable antiseptic, a saturated solution of corrosive sublimate in glycerin, a fluidrachm of this solution being sufficient to convert about four pints of water into a one-in-a-hundred solution." The journal suggests that a more handy way of carrying corrosive sublimate is to have it made up into powders, each containing ten grains of the sublimate and an equal quantity of ammonium chloride. One of these powders, dissolved in a pint of water, forms a solution of the strength of about one in a thousand. The ammonium salt is added on account of its property of rendering the sublimate more soluble.

Antipyrine.—Dr. Rank, of Stuttgart ("Berliner klinische Wochenschrift"), has employed this remedy in fifty cases, and draws the following conclusions: 1. It is a safe and prompt antipyretic in all diseases attended with fever, especially pneumonia, pleurisy, typhus, acute rheumatism, erysipelas, and tuberculosis; and it is not productive of unpleasant after-effects. 2. The temperature is more rapidly lowered after hypodermic injections of the drug than after its internal use. 3. Two grammes should be given as a dose hypodermically, and from four to six by the mouth. In general, antipyrine commends itself by reason of its rapid action and its cheapness, and it may be regarded as a substitute for quinine.

Antipyrine in Diseases of Children.—In the same journal Dr. Penzoldt commends this drug, not only on account of its rapid action, but because of the ease with which it can be administered. As a rough rule, the dose may be regulated according to the age of the patient—one decigramme for each year. The antipyretic action of the drug is secured equally well when it is given by the rectum as by the mouth, but the dose must be at least five times as large. It is to be noted that the pulse does not sink in the same ratio as the temperature, but to a much less extent.

Kairine.—M. Dreby, of Lyons, as quoted in the "Lancet," states, as the result of a series of experiments with this drug, that it can be given in doses of from six to eight grammes, especially in meningitis, acute rheumatism, and typhoid fever; that it is an efficient antipyretic, even when quinine fails; that it acts "by lowering the activity of the tissue changes"; and that ill effects from its use are rare.

Iodoform in the Treatment of Tuberculosis.—In a letter to the "British Medical Journal," Dr. G. H. Mackenzie states, as the result of his observations, that this drug, while it has been proved to cause an increase of the body-weight in phthisis, has no action whatever upon the bacilli of tubercle. "I am in a position to state," he says, "that, whatever its method of administration, and even when pushed to such excesses as to induce mental excitement, in no single case can it be said to have any effect upon these germs." He thinks, however, that iodoform and morphine form a good local application in laryngeal phthisis.

Willow Charcoal in the Treatment of Diarrhoea.—Dr. S. W. Smith writes to the same journal that he has had some experience with this

preparation on shipboard. He advises its use in cases of what he calls "fermentation diarrhoea."

Lotions for Mercurial Stomatitis.—The following formula is given in the "Union Médicale":

Tincture of iodine	4 grammes.
Cinnamon-water	50 "
Syrup of cinnamon	20 "
Distilled water	250 "

To be used as a mouth-wash. If the breath is fetid, the following mixture may be substituted:

Chlorine-water	10 grammes.
Decoction of althæa	300 "
Honey of roses	40 "

Pills for Habitual Constipation.—The same journal gives the following formula:

Extract of Socotrine aloes	1·80 gramme.
Pure ox-gall	1·20 "
Resin of podophyllum	0·15 "

To be divided into ten pills. One pill to be given every evening. As an occasional remedy, a pill may be given morning and evening.

The Infectiousness of a Dead Body.—The "British Medical Journal" says: "There seems a probability of a case of some interest to medical officers of health being brought before the courts. At the Tredegar County Court, in July last, an action was brought by a small grocer, living at Abertillery, against the Medical Officer of Health to the Abertillery Local Board, for the recovery of £50 damages for, as it was alleged, illegally preventing him removing his step-child (dead of malignant scarlet fever) by railway-train for interment in the adjoining county of Glamorgan, at Witchurch, near Cardiff, thereby, it was said, wounding his feelings and causing him pain. The county-court judge, without entering into the case, ruled that cause of action did not lie against the defendant, but against the railway company. He, however, granted the plaintiff's lawyer permission to take a case for argument before the courts in London, providing both sides could agree as to facts. It appears that, on January 20th, the plaintiff's step-child died of malignant scarlatina. The following day it came to the knowledge of the sanitary officer that the parents intended removing the corpse by rail thirty-four miles for burial in the adjoining county. Upon this information the medical officer, looking to the very infectious character of the disease, considered it his duty to warn the station-master against conveying the body in this manner, the effect of which was that it was taken in a vehicle by road to the place of sepulture. As the case appears likely to be heard of again, we refrain at present from any remarks on the medico-legal aspects of the case."

A Further Note on Cascara Sagrada.—Under this title, Mr. J. Fletcher Horne, F. R. C. S. Ed., writes to the "British Medical Journal" as follows:

"In the 'Journal' of March 10, 1883, I published a short notice of the use of *Cascara sagrada* in constipation, showing its use in almost all cases of constipation, particularly those dependent on defective, perverted, or excessive action of the liver, combined with indigestion. Eighteen months' further use, in several hundred cases, has fully satisfied me of the value of this therapeutic agent, and its right to a prominent position as a peculiarly suitable remedy in most cases of constipation. I have also been much pleased with its efficacy in the treatment of hæmorrhoids. By its action upon the portal system, its use often relieves the pain and congestion in those patients who decline surgical treatment. In several cases of hæmorrhoids, following delivery, the use of *Cascara sagrada* for a few days rapidly produced a cure. Combined with glycerin, I find children take it readily; and, as it produces full, easy stools, without nausea, tormina, or tenesmus, it excels castor-oil, senna, and other allied laxatives, as, after its use, the constipation is cured, and not increased.

"I use the fluid extract, prepared by Parke, Davis & Co., of Detroit, in doses, for adults, of from twenty to thirty minims three times a day in sweetened water; and my further observations lead me to think that the best time for administration is half an hour before meals. I feel confident that, after a trial of its virtues, *Cascara sagrada* will find many new friends in the profession."

Original Communications.

THE ASIATIC CHOLERA,

AS IT APPEARED AT SUSPENSION BRIDGE, NIAGARA COUNTY, N. Y., IN JULY, 1854, AND ITS LESSONS;

WHAT WE KNOW OF THE CHOLERA.*

By FRANK H. HAMILTON, M. D.

It seems to me opportune, when the presence of the Asiatic cholera in Europe renders it possible if not probable that it will before long again visit our Continent, to fulfill a promise made thirty years ago to Dr. Sanford B. Hunt, then editor of the "Buffalo Medical Journal," that I would prepare a paper on the cholera as it appeared at Suspension Bridge in the summer of 1854;† and to supplement this with a brief summary of our present knowledge upon this subject.

From 1849 to 1854 there had been several severe epidemics of cholera at Buffalo, but they had never extended in any noticeable degree to the neighboring towns until the year 1854. On the eighteenth day of July of this year the first case occurred at Suspension Bridge, a small village twenty-two miles from Buffalo, and about two miles below Niagara Falls. In a few days it had spread through the village, and especially among the laborers employed by Mr. Roebling in the construction of the bridge, which was then near its completion.

Of the virulence and fatality of this epidemic, Dr. Hunt, who had made three visits to the village, and, therefore, testified as an eye-witness, wrote as follows in the "Buffalo Medical Journal":

"It is also our duty to record a most fatal visitation of cholera at Suspension Bridge, near Niagara Falls. Probably no locality in this country has ever suffered so severely, unless we except Sandusky. But it is doubtful whether even that epidemic, terrible as it was, equaled in fatality, and in the mournful and shocking character of its incidents, the one at Suspension Bridge."

Dr. Hunt then proceeds to give a brief account of his own personal experience. "Many survived," he says, "but six hours after the attack, while in some instances there was no premonitory diarrhea." . . . "The panic was indescribable. Patients went into collapse immediately after their attack, while some perished from congestion." . . . "Treatment, in the majority of cases, availed but little. Nurses could not be procured on the Canada side, and in our rounds on that shore we frequently found men left alone, with a bucket of water by their side, to die uncared for." . . . "Four dead bodies were, in one instance, disposed of 'by burning the shanty in which they lay.'"

Dr. R. J. Rogers was at that time the only physician practicing in that village; and he remained on duty from the beginning to the close of the epidemic, giving himself

little or no rest day or night, until compelled to do so in consequence of his own illness. In reply to a letter recently addressed to him, he writes as follows:

"MY DEAR DOCTOR: I take the first leisure to reply to your letter asking information in reference to the remarkable cholera epidemic which prevailed at this place in July, 1854. The minutes and records I made at the time have been destroyed or lost; but the events of those few days were so stamped upon my memory that a quarter of a century has failed to efface them.

"The visitation was remarkable for the suddenness of its appearance, its short duration, the number of cases, and its terrible fatality.

"About the 15th of July a company of German emigrants were *dumped* upon the banks of the river from the cars, awaiting transportation across the then unfinished bridge. Two or three cases of what were called cholera morbus were reported to me, and, on visiting them, I found unmistakable symptoms of Asiatic cholera. One of them died in a few hours and was left for burial, while the rest of the sick were sent West with their party that evening. On the second night from this—the 20th—a sick traveler or tramp applied at the Bellevue House, kept by Mr. Sock, and, as you will remember, situated under the hill near the bridge, and was refused admission. He sought shelter under a shed in the rear of the house, where he was found dead in the morning. This was the second case recognized as cholera. That same day a ship-carpenter, working on the steamer New Maid-of-the-Mist, was attacked and died in about thirty hours. The vessel was then being constructed at the landing on the river, just below the Bellevue House. On the same day, also, three laborers, boarding at the Bellevue House, died of cholera; and on the 21st or 22d the mother of the hotel keeper died after a few hours' illness. Almost simultaneously with this case and directly opposite, in a shanty on the Canada side of the river, the wife of an Irish laborer was taken sick and died that afternoon. They had a wake that afternoon over the corpse (which means whisky), and, of those engaged in the wake, five died of cholera within twenty-four hours.

"I mention these as the preliminary cases only, for after this the cases multiplied rapidly. On the night of the 24th four strong, healthy men, two of them foremen or overseers, were attacked, of whom three died within twenty-four hours. This was the most fatal night and day, and the cases had become so numerous that it was impossible for me to see them all, much less to give them the needed attendance. By this time also the people had become panic-stricken, and as many as were able fled with their families, thus leaving fewer victims for the disease to feed upon.

"It was almost impossible to get at the number attacked, but it has been ascertained that there were at least eighty deaths on the two sides of the river; and, when we consider the proportion which this number bears to the actual population at that time, this result is appalling. When the disease broke out there were not more than eight hundred on the American side and perhaps five hundred on the Canada side, of which entire number probably five hundred left

* Read before the New York Academy of Medicine, November 6, 1884.

† "Buffalo Med. Jour.," vol. x, p. 181.

almost immediately. We have, therefore, to record the terrible fact that the actual population was decimated by the disease in about ten days.

"Much was said and written at the time by medical men as to the probable cause of the virulence of the epidemic; but, in order to a full understanding of this matter, it will be necessary to state that more than nine tenths of the victims resided on the narrow flats bordering the banks of the river on both sides. Of these, fully one half were employed in the construction of the bridge—wiremen, blacksmiths, and carpenters. Three of the four gatemen died.

"During the whole prevalence of the disease the weather was excessively hot. There had been frequent rains, and the water stood in pools around the shanties, that were huddled pretty close together on the low ground. These, having been hastily constructed, with perhaps one door and one window, were deficient in light and ventilation. All who occupied this low ground, on both sides of the river, used exclusively the water obtained from a sulphur spring situated near the bridge on the American side. This water was clear and cold, and flowed in a copious stream—probably several gallons a minute. Apparently it contained nothing prejudicial to health, but it was strongly impregnated with sulphur.

"The strip of flat land which we have described is, on the American side, from forty to fifty rods wide. The soil, which is so thin that the rocks come to the surface in many places, is clay, covered with a slight layer of muck or alluvium. Across this a large open sewer had been dug to the bank of the river, but this was not yet in use. From the low ground there arose abruptly, to the height of about twelve feet, and extending parallel with the river, a bank, composed of red clay and terminating above in a plateau or level plain, which extended back into the country several miles, through which there had been made recently numerous excavations for railroads and buildings.

"After the disease began to subside, on examination, under the Bellevue House a large amount of filth was found to have accumulated, and also stagnant water. There was no cellar. Two men, brought from Lockport, were employed to clean the premises and remove the filth, and both of them died in a day or two of cholera. I do not remember that any other premises in that locality were found so bad.

"In localizing the disease more precisely, I will state that it was confined mostly to a very small area, not averaging more than a hundred rods in width, and perhaps twice this distance in length, on both sides of the river. There were a few cases among those who had fled from the disease a mile or two back in the country; notably among the latter was the proprietor of the Bellevue House, whom, you will remember, you were called to see, and who died that night.

"One remarkable feature of the epidemic was that, in a majority of the later cases, there was an absence of the usual premonitory symptoms, many of the patients being in collapse within an hour. In the earlier cases, however, there was the usual vomiting, and then rice-water discharges, accompanied with no pain usually, but with great lassitude and dejection, followed by cramps, confined most-

ly to the muscles and tendons of the toes, a gradual lowering of the temperature, profuse sweating and great thirst, the skin assuming a leaden color and losing its contractility, the pulse deserting the wrist, the tongue becoming cold, and the voice husky. As the period of unconsciousness approached, there would be restlessness, and, long after the cessation of the pulse, there would be considerable muscular activity. During the two or three most fatal days I would find the patients within a few hours of the attack with a cold tongue and pulseless, and with such a degree of hoarseness that they could only speak in a whisper, and still they could get up and walk about the room. Some had no vomiting or purging, and lived but a few hours.

"Of all the fatal cases, but five occurred in that portion of the village which was situated above the lower plain just described. The last died on the 30th, and this person was the wife of the writer.

"I have now, my dear doctor, given you all that is within my recollection, and perhaps all that is pertinent to your inquiries. I ought to add, however, that I think we estimated at the time that at least 70 per cent. of the cases proved fatal.

"As to the treatment, I will only state that the efforts to restore warmth to the surface by irritation, or by hot applications, or by stimulating drinks administered internally, were never attended with any satisfactory results; nor would they restore but temporarily the flagging circulation or the sinking pulse. Swathing the patients in wet sheets was thought at first to be beneficial, for it removed the dark leaden color of the skin almost immediately and restored the natural color, the absorption of the water compensating, in a measure, for the loss of the serum of the blood; but in the end it all seemed 'vanity of vanities.' Homeopathy and hydropathy were alike tried by one or another of the sufferers, and they alike failed. The latter form of treatment was tried most thoroughly by Mr. John A. Roebling, the distinguished engineer. He was a great admirer and personal friend of Preisnitz, and, fully believing in his theory, on the morning of that very fatal day he improvised a hospital and had eight patients subjected to that form of treatment, but they *all* died before night.

"If you can glean sufficient from this long letter to give interest to your article I shall feel compensated, for I have always felt grateful for the valuable assistance you rendered me on that trying occasion, as well as to your two distinguished associates in the medical profession, Dr. Sanford B. Hunt and Dr. Thomas F. Rochester. The former was with me three days, and made a short but interesting report of the epidemic in the 'Buffalo Medical Journal,' of which he was then the editor.

"I am very respectfully yours,

"R. J. ROGERS."

The foregoing narration of the circumstances and events connected with this epidemic, not originally intended for publication, but now published by the writer's consent, is so complete and graphic, and furnishes such an exact portrait of what came under my own observation, that I am relieved of the necessity of doing more than to give it my

indorsement, and of adding a few facts communicated to me by Dr. Rogers in subsequent letters, together with a few more drawn from my own personal experience and recollection.

Dr. Hunt, Dr. Rochester, and myself visited Suspension Bridge in response to a request made by Dr. Rogers to the physicians of Buffalo that they would come to his relief, as he had become completely exhausted, and was unable any longer to answer the unceasing demands which were made for medical services. Our visits were made alternately and on successive days, my visit being made, I think, on the 23d, and extending through a portion of the 24th, at which time the epidemic was about at its height of malignancy and of fatality.

Arriving at the house of Dr. Rogers in the afternoon, I left Mrs. Hamilton, who had chosen to accompany me, in the care of Mrs. Rogers, of which estimable lady Dr. Rogers has spoken in his letter as being the last person in the village who, five or six days after my visit, succumbed to the disease. I then proceeded at once to answer two or three urgent calls in the upper village, which was composed of about thirty comfortable residences, and in one of which the patient had died a few minutes before my arrival.

Returning to Dr. Rogers's house, I found Colonel Fiske, subsequently made president of the village, waiting to go with me to the lower village, or "Shantytown," as I shall call it by way of distinction.

Together Colonel Fiske and myself visited almost every house which was occupied, in most of which were one or more sick, or dying, or dead. A number of families had fled hastily, leaving their effects unprotected in their houses. In one shanty lay a dead woman upon a bed, and she was the sole occupant of the house.

Remedies, so far as they seemed to be indicated, were administered from the small satchel supplied with medicines and restoratives which I carried with me; but the principal duty which seemed to devolve upon me, and in this I was seconded by Colonel Fiske, was to urge the people to get away. In many cases this seemed to be impossible. They were poor, and they would have to carry with them their aged parents and young children—their sick and dying and dead; and they must leave the little property they had behind them. If conveyances could be procured, who would take the risks of removing them? Who would receive them into their neighborhood with their load of pestilence? Although I thought then, and do now, that the danger of communicating the disease to other persons in places where the sanitary conditions were more favorable was very small; but those living in the neighborhood of the infected district no doubt thought differently.

That night I was called to Plitcher's Corners, three miles into the country, to see Mr. Sock, the keeper of the Bellevue House, Shantytown, who had fled the day before, but not until his wife had died. In him also the seeds had been planted before he left the Bellevue House, and I found him in collapse. He died in a few hours. Dr. Rogers has been unable to learn whether any members of the family in which Mr. Sock died, or any of the neighbors living in the same village, were affected with the disease or not, but it

may be assumed that they were not, inasmuch as Dr. Rogers would certainly have been called to attend them in case they had been.

On returning from my visit to Mr. Sock, although the day had not begun to break, I found new messages from Shantytown. By the aid of a lantern I again visited many of the houses. Several new cases had occurred; some that I had seen before were dead, and a few of the older cases were slightly better. The air was more close and stifling than it had been during the day. Outside one of the shanties near the bridge—it was now broad daylight—lay a man suffering from cholera who had been refused admission by the woman who occupied the shanty, and I was unable to change her decision. Walking thence across the bridge—and this was the first time I had been able to answer the calls from the Canada side—and going from shanty to shanty, I found the condition of the occupants much the same as I had found them upon the American side. In two of the shanties wakes were in progress.

Returning to the house of Dr. Rogers, and continuing to attend to the calls of such as asked for medical aid until after mid-day, I then left for Buffalo.

I will mention, as additional facts worthy of note, that there had been a protracted drought, followed within a few days preceding the epidemic by copious rains, and that, consequently, as mentioned by Dr. Rogers, the water stood in pools here and there on the low grounds. An open drain had been recently constructed from the Monteaule across the low ground at the north end of the collection of shanties on the American side. From this a good deal of fresh earth had been thrown up, and still lay exposed.

The Monteaule was then being constructed about one hundred rods north of the bridge, and on the highest ground of the neighborhood. Only one person fell sick of cholera who was employed upon this work. There were no shanties near the sulphur spring, and none so situated as that their refuse water or the human excreta could drain into it. This spring was considered so valuable by Mr. Roebling that he subsequently had constructed for it a granite basin, inclosing it with a railing, and it can now be seen just north of the bridge abutment on the American side. Its source is from underneath the abutment. Its flow is less abundant than formerly, and it is less strongly impregnated with sulphur.

On the Canada side, also, extensive excavations had been made, and the ground upon which the shanties were built was much lower than the adjacent ground.

During the progress of the epidemic two or three cases of cholera occurred at Lewiston, a few miles below, and about the same number at Niagara Falls, two miles above. In the latter place it occurred among the laborers employed in excavating a hydraulic canal. It is most probable that the germ was conveyed to both of these places by fugitives from Suspension Bridge, but the disease found no soil proper for its germination, and it died out.

The Bellevue House stood upon piles, two or three feet high, having no cellar, and a good deal of filth had accumulated underneath. In the neighborhood of the shanties there was some degree of uncleanness, but no more

than is usual in such settlements. Many of the shanties, being quite near the precipitous bank of the river, had a natural drainage, which was much to their advantage. In my visits I did not notice any unpleasant odors.

As early as practicable after the commencement of the epidemic disinfectants were procured, and employed freely in and about the dwellings.

There are certain inferences which may be made from this experience, and there are certain lessons taught by it which ought not to be forgotten. It is not pretended that these lessons are new, but only that they have been presented in this instance in such an impressive manner as to entitle them to special notice.

Before attempting to point out and enforce these lessons, I will state briefly what, in my opinion, is the present state of our knowledge upon the main points relating to the nature, ætiology, mode of propagation, and treatment of Asiatic cholera.

WHAT WE KNOW ABOUT CHOLERA.

1. We have no positive knowledge of the existence of a specific cholera-germ.

While the existence of a specific cholera-germ, endowed with the principle of life and capable of growth and propagation when supplied with its proper nutriment, is rendered probable by many facts and analogies, yet such a supposition has not been established by strict scientific observation or reasoning.

I employ the term "cholera-germ," then, only as a substitute for "cholera-infecting material," whatever that may be, and as the term which most nearly expresses my belief as to its nature.

2. So long ago as 1854 or 1855, Professor Filippo Pacini, of Naples, published, in the Italian "Medical Gazette," a paper on cholera, in which he describes a germ or microbe, and to whose presence he ascribed the epidemic cholera. His paper was translated into French and English, and republished in 1865, 1866, 1871, and 1879.

Koch has more recently (1883) discovered in the intestinal secretions of cholera patients a bacillus or spirillum, designated usually as the "comma" bacillus or spirillum, which, so far as his observations have extended, is uniformly present in well-defined examples of cholera, and is not found in any other conditions of disease or of health.

Dr. H. Vandyke Carter, of Bombay,* has found an organism which it is conceded resembles very much the comma microbe of Koch. The presumption seems to be that it is the same, but of which microbe Dr. Carter says that it was not uniformly found in cases of cholera, and that it was occasionally present in cases of diarrhœa and dysentery.

Dr. Maurin and Dr. Lange, as the result of their studies at Marseilles,† announce that they have discovered a mucus, which, in the process of its development, germinates spores, and these in turn germinate a new form of mucus, termed

anaërobium; these latter, sporifying, give birth to the bacilli of Koch; and, finally, the bacilli develop the original mucus, and thus the cycle of life and development is completed. They regard the second form of mucus or anaërobium as the immediate cause of the phenomena of the disease, while they regard the bacilli of Koch as innocuous.

Dr. T. R. Lewis, of the British army, assistant professor of pathology in the army school at Netley, has been studying the cholera also at Marseilles, and he reports as the result of his investigations that the comma bacillus is present in all well-developed cases of Asiatic cholera, but that he has found it also in the salivary secretions of healthy persons.*

It is also stated as a fact, tending in some measure to corroborate the opinions of Koch, that two Swiss physicians, Ritsch and Nicati, experimenting at the Pharo Hospital, Marseilles, under instructions from the French Government, have caused the Asiatic cholera in rats, Guinea-pigs, and dogs by injecting the dejections of cholera patients into the duodenum after tying the ductus choledochus, hoping in this way to prevent the action of the gastric secretions and the bile upon the bacilli.†

Certainly such statements ought to be received with a great deal of hesitation. So far as I am informed, none of these animals have been known to take the cholera under ordinary exposures, and the Egyptian Commission was unable to produce it by inoculation or injection in cats, dogs, mice, rabbits, or hens.

Dogs are the almost universal companions of men in all countries, both in health and sickness, and their habit of eating all kinds of decaying and filthy substances, including human excreta, is well known, yet I have never seen a case of cholera among dogs, nor do I know that any one else has. That these animals should have had some sort of disturbance of the bowels after the severe surgical operations to which they were subjected is quite probable, but that this was of the nature of Asiatic cholera is not, in the light of our experience with dogs, at all probable.

A correspondent of the "New York Times," in a cable dispatch, says that Dr. Klein, a Bombay official and expert, has experimented upon himself by swallowing a quantity of the comma bacilli, and without harm.‡

Professors Finkler and Prior, of Bonn, announce that they have discovered the comma bacillus in the stools of those suffering only with cholera nostras, or cholera morbus.*

Straus, Roux, Rocard, and Thuillier, pursuing their investigations under the authority of the French Government in Egypt during the month of August, 1883, declare, for reasons which they assign, that they do not feel themselves justified in concluding that the comma bacillus of Koch is the cause of cholera.||

Finally, MM. Sicard, Taxier, Loucel, Livon, and Charreyre, members of a commission appointed by the French Academy, and who pursued their investigations at Mar-

† "Med. Record," September 27, 1884, p. 350.

seilles, report that the blood of a cholera patient injected into the veins of a rabbit will cause cholera; the perspiration thus injected does not transmit the cholera; the intestinal contents, loaded with bacilli, do not transmit the cholera when injected into the cellular tissue of the peritoneum, into the windpipe, into the blood, or into the intestines; that the comma bacillus is not the cause of cholera; and they conclude by saying: "We know better than our predecessors what the cholera is not, but we do not know what it is."*

We are at least permitted to say, in view of the conflicting testimony to which I have referred, and of many other statements made by less conspicuous observers, that the theory of Koch that the comma bacillus is the cause of cholera has not been established.

8. Even if it were established that the comma bacillus was always present in cholera and never present in any other condition of health or of disease, it would not determine the question whether this bacillus stood in the relation of cause or effect.

4. The theory is defective, also, in that it has not been shown that the ingestion or reception into the human system of excreta containing the comma bacillus will produce the cholera. On the contrary, if we can accept the current reports, there is at least the testimony of one experimenter that it will not.† The inoculations practiced by Koch himself were barren of results.

5. If the fact were demonstrated that the ingestion of choleraic discharges containing either of the microbes mentioned would cause cholera, the question would remain which of the microbes hitherto described was the efficient agent, or whether any of them were, or indeed whether it was not some microbe for the discovery of which the microscope has not yet been invented; and, finally, whether it is a germ of any kind, or only the fluids in which they are contained, and which have undergone some peculiar changes, for the detection of which no microscope hereafter constructed may prove sufficient. By successful inoculation of the germs alone, after they have been completely isolated by cultivation, could they be proved to be the cause of cholera, and this has not been done.

I do not wish to underestimate the importance of microscopic studies; nor can I always accept of the estimate which some seem disposed to place upon them. They have added greatly to our knowledge of disease, and give us encouraging promise for the future; but, so far as cholera and a majority, to say the least, of other epidemic and infectious diseases are concerned, they have not taught a single lesson either in the prevention or the cure. Their germicides kill the microbes when they are attacked outside of the body and removed from their native element, but they are harmless to them when the assault is made inside the human body; consequently, the unfortunate patients continue to die since the supposed discovery of the parasites the same as before.

It is not positively determined that the infecting mate-

rial is not hereafter to be found in the blood or tissues of the body, in the breath, or in some other secretions than the intestinal. The experiments of the French Commission would at least seem to show that it is in the blood.

When, therefore, Koch places in contrast the results of microscopic investigations and the results of experience, declaring that the latter has not taught us the successful treatment of cholera, he permits the reader to draw an unfair inference. The contrast is not unfavorable to experience, inasmuch as it has taught us something, indeed, as will hereafter be shown, a great deal in reference to the treatment of cholera, while microscopical studies have taught us absolutely nothing.

6. The cholera-germ may be conveyed from place to place by clothing or any other textural fabrics, by articles of food, or by water, and by many other animate and inanimate substances.

7. It may be conveyed for considerable distances by the air. How far it can be thus conveyed it would be impossible to say, but probably much would depend upon the force of the wind and other atmospheric conditions. There is, no doubt, a limit to its conveyance by this method, and I have reasons to believe that it can not be thus conveyed beyond a mile or two.

Those who have denied, or permitted themselves to doubt, that cholera can be thus conveyed have, it seems to me, either been inexperienced, or they have closed their eyes to the testimony which the experience of almost every epidemic supplies in such abundance.

8. The theory of Koch that the germ only finds its way into the system through the mouth and stomach is the necessary corollary to his belief that the comma bacillus is found only in the alimentary canal, and that it is the true germ or cause of the disease, and the only medium of its propagation; but it can not be inferred from any facts observed by me in the histories of those epidemics in which I have had a personal experience, nor from anything I have seen recorded in my studies of this affection. That it may be one of the modes of propagation may be admitted, but that it is the sole or even the principal mode of propagation has no foundation other than Koch's unproved, and to me improbable, theory that the comma bacillus is the true germ of the cholera.

9. There is quite as much reason to believe that it is conveyed into the system by the respiratory organs, and that it diffuses itself throughout the entire body through the circulatory system, like any other septic infection, and that the specific symptoms and the specific choleraic intestinal secretions are the results of a general systemic infection. Why the poison expends its force in one direction or another, or why, perhaps, it seeks to eliminate itself through one organ of the body rather than another, can not be explained any more than we can explain the preference of eruptive contagious maladies for elimination by the skin, and the preference of other septic infections for other organs and tissues. It certainly is not necessary to assume, because the intestinal secretions are changed and the intestinal mucous membrane is congested, that the virus was implanted originally in the intestinal canal. The blood, the per-

* "Med. Record," October 25, 1884, p. 467.

† The statement has been repeated more recently by the "Medical Record" (November 8, 1884, p. 523).

spiratory and the renal secretions, and the kidneys themselves, undergo changes quite as marked and distinctive as those which take place in the intestinal secretions and in the mucous membrane of the intestines.

10. It is probable that the cholera germ or virus, although it may have been received into the system, does not necessarily infect the system, or give rise to cholera.

It seems probable that every person living in, or even entering temporarily, a cholera atmosphere receives more or less of the virus into his system, but of those persons thus inoculated many do not suffer in any degree, and others only slightly, while a small proportion are taken sick and die.

It is true also of all other infectious diseases, that inoculation or the reception of the virus into the system does not necessarily produce the specific disease. Especially is this true of all eruptive infectious diseases. But in the case of most infectious diseases a large proportion of those exposed become infected, while in the case of cholera a very small proportion become infected. In other words, a suitable soil, or suitable conditions for the development of the germ, are usually found in the former, while in the latter they are seldom found.

We, of course, must except from this general statement, in regard to other infectious maladies than the cholera, variola in case the patient has been protected by vaccination. Cholera differs also from many other infectious maladies in that one attack affords no protection against a second.

11. The conditions requisite to render the inoculation of cholera by the ordinary methods effective are all those conditions which cause, or coexist with, disturbance of the natural secretions of the alimentary canal, including fear and other depressing mental emotions; the presence in the bowels of undigested, fermented, putrefying, or of other acrid ingesta; deterioration of the air habitually inhaled, from personal filth, and from overcrowding in ill-ventilated apartments; inhalation of the air from putrefying masses of vegetable or animal matter, from stagnant pools of water, or from soils freshly exposed; and, finally, the concurrence of a warm and moist condition of the atmosphere.

Of all the conditions enumerated as favoring the germination of the cholera germ, none are probably so efficient as the inhalation of the vapors arising from a freshly exposed soil, especially if it contains decaying vegetable matter, and the concurrence of a humid state of the atmosphere with an elevated temperature.

The poor, both in cities and in the country, mostly occupy the lowest lands. If these lands are alluvial, and especially if underlaid with clay so as to retain the moisture, they favor the propagation of cholera as well as of other diseases. The preference which most epidemics show for the habitations of the poor is therefore often susceptible of another explanation than that their personal habits are uncleanly, or that they suffer from overcrowding and bad ventilation.

In addition to the testimony furnished by the Suspension Bridge epidemic, as to the relations existing between low and alluvial soils and the propagation of the cholera, I

could add a personal experience in Buffalo and New York, but especially in the former city, through several epidemics. In Buffalo a low and *sandy* plain, bordering upon the lake and wholly occupied by Irish shanties, was almost entirely exempt.

In the report of Mr. Farr, Registrar-General of England, for 1848-'49, may be found a very full and complete statistical statement upon this subject; and after having taken into account, as contributory conditions, density of population, poverty, intemperance, uncleanness, and many other causes, Mr. Farr concludes that the influence of a low and unwholesome soil was by far the most potent exciting cause. "It has been seen," he says, "how rapidly in London the cholera diminishes a few feet above the low ground on a level with the Thames."

This observation was not made for the first time by Mr. Farr. It is as old almost as the existence of the cholera. Exceptions have been noted from time to time, as, for example, in the frequent occurrence of the cholera at Bellary, in India, where an English fort is built upon a granite rock 500 feet high; but in this case, as probably in all other similar exceptional cases, a sufficient purely local cause can be found, and the exceptions do not affect the value of the general law which has been stated.

Need I remind you, gentlemen, of the terrible fatality of this scourge at Toledo and Sandusky, Ohio, in 1849, in the latter of which cities alone seventeen physicians died of the disease? Both of these towns are situated upon low and exceedingly rich alluvial plains.

As to the effect of a fresh exposure of an alluvial soil, or of soils more or less impregnated with decaying vegetable matter, permit me to refer briefly to an experience at Buffalo.

On Saturday, July 24, 1852, a ditch was commenced for the purpose of laying pipes through Ellicott Street, Buffalo. On Monday the work was renewed, and it was opened completely on Tuesday. The excavations brought to the surface a large amount of alluvium underlying made ground of clay and sand. The cholera was prevailing in a mild form in some other parts of the city; but Ellicott Street had always been regarded as healthy, and had almost entirely escaped in previous epidemics. It was occupied by the best class of citizens. There were twenty residences upon the portion of this street corresponding with the ditch. On Monday the first case of cholera occurred among the residents, and on this and the two following days there were nineteen cases and nine deaths. The ditch was closed, by order of the Mayor, on Wednesday, and from this date there were no new cases.*

11. There has been as yet no specific discovered for the treatment of Asiatic cholera. Nor can we entertain much hope that there ever will be. Science has hitherto brought to our knowledge very few specifics for disease, and none have ever been found for any of the infectious epidemic diseases, and, considering the great number of medical men who have earnestly sought to discover a specific for cholera, and the infinite variety of medicines which have been em-

* "Buffalo Med. Jour.," September, 1852, p. 223. My report to the Buffalo Med. Assoc.

played, it would seem that there could remain but little ground of hope that it would ever be discovered.

We have learned from clinical experience, however, in the case of cholera, much more than we have learned in the case of any other infectious epidemic malady. We can not terminate abruptly or abort the small-pox, measles, chicken-pox, or scarlatina. We can only control or modify them, so as to conduct them to safe terminations at their allotted periods. On the contrary, we can and do generally abort the cholera. A large majority of those who are treated by appropriate remedies, and especially if removed promptly from the influence of predisposing causes, recover quickly. To justify a denial of this, it will be necessary to assume that the diarrhœa which, in most cases, precedes the vomiting and collapse, does not usually indicate the presence of the choleraic virus in the system—an assumption which implies that the cholera, unlike nearly all other diseases, has no admonitory prodromes. Such an assumption is unreasonable, and is not warranted by any facts of observation.

It is not often that a patient is saved to whom remedies are not applied until the algid period, or period of collapse, has arrived; but a large proportion are saved by appropriate remedies employed in the earlier stages of the disease. Dr. Yale, in the report on the cholera at Blackwell's Island, hereafter to be referred to, says that, of those brought first to the "diarrhœa hospital," not one died.

The means which have been most successfully employed are essentially those which have long been known to be successful in the treatment of diarrhœa, cholera morbus, and other allied affections. According to my observation, the remedies which have proved most efficient prior to the period of collapse are opium and absolute rest. Opium, in a solid form, should be preferred to morphine, as being less likely to provoke nausea. It should be given to adults, in doses of from half a grain to a grain, every three or four hours until the diarrhœa is restrained, or until moderate narcosis is produced. The production of excessive narcosis is seldom or never judicious, nor should the opiates, as a rule, be stopped suddenly, lest in either case nausea should ensue. Under no circumstances should the patient be permitted to rise, or even to occupy the sitting posture, after taking opium. If for any reason tincture of opium is preferred, it should be combined with tincture of ginger or some other diffusible stimulant. If morphine is used, it should be placed upon the tongue dry, and swallowed with not more than a teaspoonful of water.

As in ordinary diarrhœa, so also in the early stages of the diarrhœa of cholera, in case the stomach or bowels are known to contain highly irritating ingesta, a single brisk cathartic may be first given, and this to be followed, after a sufficient evacuation, by the opiate.

It is not intended to say that other medicines may not sometimes control the premonitory diarrhœa, but only that the writer has found the simple formula described the best.

If one should wish to render the theory of this treatment consistent with the theory of the existence of a cholera germ, it is only necessary to suppose, what seems probable, that the period of life, or of activity of the germ in the human system, is brief, and that the opium holds the secretions in

a normal condition until the germ perishes or the force of its virus is expended.

There is much clinical experience which tends to show that in the human system the period of life or of activity of the germ is brief; and to this we may add one of the conclusions of the French Commission already referred to, namely, that "the blood of a choleraic patient, by cultivation, after a few hours loses its infectious properties."

We may also, I am persuaded, diminish the severity of an attack or arrest its progress by the prompt removal of the patient outside of those atmospheric, telluric, and other influences which are known to cause the development and propagation of the cholera.

12. Removal of an infected person to a perfectly healthy region—that is, a region supplying none of the conditions favorable to the development and propagation of the disease which has been named—does not in most cases cause a propagation of the disease in that region; but, like brands scattered abroad from burning buildings, provided they are not thrown among material already in a proper condition for combustion, they usually cause no further mischief.

LESSONS TAUGHT BY THE SUSPENSION BRIDGE EPIDEMIC.

The inferences to be drawn from the Suspension Bridge epidemic, so far as they have any bearing upon the opinions expressed in this paper, are confirmatory. They may be briefly stated as follows:

1. The cholera germ was brought by the emigrants who were temporarily detained near the settlement of laborers, the first case occurring among the emigrants. So far as can be learned, the emigrants had not suffered from the cholera before, nor did they after leaving Suspension Bridge. Upon this point our information is not positive and definite; but, at any rate, I feel justified in saying that the cholera, if it existed among them before or after their detention, was not in such a degree as to attract the attention of the railroad officials or of others; and this is all that it is necessary to establish for the purpose of my argument. It exhibited no virulence until it was communicated to the Suspension Bridge laborers.

2. That the emanations from a large amount of lately upturned soil, containing more or less decaying vegetable matter, contributed to the propagation and malignancy of the disease.

3. That the elevated temperature, together with the moisture of the atmosphere, constituted an important factor in the causation—a condition, however, which was not limited to this precise locality, although on these low lands bordering the river these conditions were most intense.

4. Dissemination of the infected, or of those persons who might be presumed or were known to carry with them the cholera-germ, did not propagate the disease—or at least in only a very few instances—to places where the topographical conditions were more favorable—and in these isolated examples no epidemics resulted.

WHAT HAVE WE TO APPREHEND IN CASE IT APPEARS AGAIN IN THIS CITY?

To the question which may appropriately be asked in this connection, In case the cholera reappears in this city,

is there danger that it will prove as destructive as it has proved to be in the last epidemics at Naples, Toulon, Marseilles, and in some other towns of Southern France and Italy? I reply, No; and for the reasons that our climate is more favorable, our system of sewerage is better, there are no portions of the city which are relatively so low as to become the recipients of the drainage of the higher portions, we have a smaller proportion of very poor and personally unclean citizens, and, finally, because experience has shown that here, at least, the prompt application of judicious sanitary measures is certain to prevent the spread of the disease.

It would be an affectation of modesty on my part if I were to omit to refer, in confirmation of this statement, to the sudden and violent outbreak of cholera which occurred in the Workhouse on Blackwell's Island, and to its speedy arrest under the application and enforcement of sanitary measures.

The cholera had appeared in great severity and malignancy at the Workhouse, and was spreading rapidly over the Island. On the 1st day of August there were 29 new cases and 10 deaths at the Workhouse. On the 2d there were 33 new cases and 14 deaths. I was at that time chairman of the Committee of Inspection for the Islands, and on the morning of this day the Commissioners of Charities and Correction placed Blackwell's Island unreservedly under my control, so far as its sanitary condition was concerned. On the next day the most important sanitary changes had been made, some of which were very radical, and were in operation. At the close of this day there were reported 30 new cases and 13 deaths; on the following day, August 4th, there were 21 new cases and 4 deaths; on the 5th there were 12 new cases and 7 deaths; on the 6th there were 4 new cases and 3 deaths, and on the 7th, 1 new case and 1 death. Thereafter, until September 23d, a period of forty-six days, there were 27 new cases, or considerably less than one a day, after which it ceased altogether.

Dr. Leroy M. Yale, who was at that time one of the fourteen house surgeons upon the Island, and who remained on duty to the close of the epidemic, made, by request of the Commissioners, a report upon the subject of the epidemic. This report, published subsequently by the Commissioners, is remarkable for the minuteness and accuracy of its statistical labor, and for the value of its many and carefully drawn conclusions. On the 7th day of August, the fourth day after the introduction of the most important sanitary changes, he reports, "the epidemic was virtually at an end."*

But this illustration of what may be accomplished, at least in our climate, is unimportant as compared with what has been done in this great city by the intelligent and energetic action of our Board of Health. Again and again the cholera has appeared in the lower parts of the city, and especially in our crowded tenement-houses, and as often has it been confined to the narrowest limits or speedily "stamped out."

In concluding, gentlemen, I wish to repeat, what I have

intimated before, that I know too well the value of the services which the students in microscopy have rendered to our difficult science to permit me to say one word which could in any way be construed into a lack of appreciation of their skillful, painstaking, and, in this country generally, unrequited labors; but, while we are hopefully waiting the disclosures of this important branch of our science, we must not neglect to give attention to the suggestions and demonstrations of clinical experience, especially when, as in the case of the Asiatic cholera, they have not been by any means barren of practical results.

NOTES OF A CASE OF DERMATITIS HERPETIFORMIS DURING THIRTEEN YEARS.

BY LOUIS A. DUHRING, M.D., PHILADELPHIA,
PROFESSOR OF SKIN DISEASES IN THE UNIVERSITY OF PENNSYLVANIA.

THE notes here presented, portraying the disease I have named dermatitis herpetiformis, are of such interest that they are given in full, with the view of directing attention to the many and peculiar phases this remarkable disease may assume. The long period the disease was under observation and the extended notes, which were made at the time, give us valuable information on the natural course of the disease—a point always of importance in the study of cutaneous affections:

H. H. McK., aged thirty-one, an American, and a painter by occupation, was admitted to the Philadelphia Dispensary for Skin Diseases, Philadelphia, July 6, 1874. He was in impaired health, and had been suffering from the skin disease for which he sought relief since 1871—a period of three years. He was of small frame and spare, and was apparently in a state of nervous exhaustion, being weak, tremulous, dyspeptic, and despondent about his condition. He was married, and was temperate in his habits.

The following clear history was obtained: In 1871 the first disease of the skin ever experienced manifested itself in the form of lesions which he describes as "hives." They came unexpectedly and suddenly, and occupied every portion of the surface except the face, being particularly numerous and thickly set about the elbows and knees. They were erythematous in character, and were split-pea and finger-nail sized, raised, and flat. Some were discrete, but the greater number were confluent. The whole surface was pretty well covered with the efflorescence, and was the seat of violent itching. The attack is described as having possessed all the features of urticaria. It gradually subsided in the course of three or four days, when a crop of small, rounded, flat *pustules* began to appear here and there, especially about the knees and elbows, accompanied by itching. They increased slowly in size, and crusted with a brownish, adherent crust. A number of them came out, varying in size from a split pea to a small finger-nail. They all ran a similar course, lasting from five or six days to a fortnight. By the end of four weeks they had completely disappeared, but, almost before the crusts of the earlier lesions had fallen off, a crop of *vesicles* and *blebs*, of all sizes and shapes, suddenly appeared, distributed quite generally over the extremities and upon the face. There were great numbers of them upon the face, and they varied in size here from a pin-head to a hazel-out. Upon the general surface they were mostly small—pin-head and

* Annual Report of the Commissioners of Public Charities and Correction, 1863, p. xv; also pp. 109-197.

split-pea sized. Some were raised and semi-globular in form; others were flat. The lesions, as stated, were *vesicles* and *blebs* having perfectly clear contents, and were without areolae. They were very itchy. There were no signs of pustules.

This attack lasted about two months, new vesicles and blebs appearing from day to day, and gradually subsided. The patient speaks of the experience as having been very trying, not only on account of the presence of the lesions and the discharge and crusting, but also because of the itching.

For several months he remained comparatively well, when a copious mixed eruption—composed of small *vesicles*, *pustules*, *vesico-pustules*, and *vesico-papules*, accompanied with itching—made its appearance upon the regions previously affected. This was the first occasion of the lesions being distinctly multiform. This attack lasted only a fortnight, vanishing quite suddenly, and leaving the skin in a better state than for months. This last form of eruption, however, soon recurred, lasting, as previously, but a few weeks, and, as before, leaving him apparently quite well. He has had many attacks of this character, at intervals of a few months, up to the present time. The disease has thus continued its course, uninfluenced by the varied treatment to which he has been subjected. He does not think that the seasons have at all influenced the natural course of the disease.

It was at this period (July, 1874) that the patient first presented himself to me. He showed the pustular phase of the disease, which had but recently made its appearance. There were about a score of disseminated, split-pea and finger-nail sized, flat, mostly crusted with a yellowish-brown, adherent, flat, ecthyma-form crust, here and there distinctly clustered *pustules*. They occupied the lumbar and sacral regions, the buttocks, and the elbows and knees. They had appeared a fortnight previously, and had been and were still accompanied by itching. The more recent lesions I observed were surrounded by bright-red, highly inflammatory areolae, and were peculiar in that they inclined to crust in their center and to spread on the periphery, forming more or less distinct, narrow rings of pustulation immediately beyond the line of the crust. This feature was not constant, but existed in connection with a number of the lesions, and constituted a symptom which at once arrested my attention.

The case was regarded as an unusual one, the form of disease being entirely new to me, and this observation was so recorded in connection with the notes. The lesions bore a close resemblance to cachectic ecthyma, but the localities attacked were those seldom invaded in this latter disease. The pustular variety of eczema, aggravated by some irritating application, also suggested itself, as did, moreover, impetigo contagiosa. The contents of several of the pustules, as well as the crusts, were at the same time submitted to microscopical examination with a view of determining if any parasite was present. The patient was placed upon a saline laxative mixture, together with full doses of the tincture of chloride of iron. No local treatment was ordered. The case remained under observation three months, and, according to the notes recorded, the patient was in about the same condition at the expiration of this period as upon admission; the skin, however, underwent several decided changes during the three months, having been on one occasion almost well, but the lesions soon reappeared. The disease did not seem to be in the least degree influenced by treatment, whether internal or local, new pustules, small and large, appearing from week to week. In November, 1874, he ceased attending the dispensary, much discouraged. The diagnosis was as obscure at this time as on admission.

In January, 1879, four years after the foregoing note, he presented himself for treatment at the Hospital of the Univer-

sity of Pennsylvania. I at once recognized my former patient of the Dispensary for Skin Diseases. He stated that he was still afflicted, but that until recently it had existed in a milder form, and that he had experienced intervals of from one to six months of comparative freedom, but he had never been entirely free of eruption. The general health had failed considerably, the nervous system had become more disturbed, and he was habitually constipated. During the four years he had employed various internal and local remedies, but without benefit. The general course of the disease had been about the same as when under observation four years before. He had noted four kinds of lesions, which would manifest themselves together or in different attacks of eruption; these were true *pustules*, containing from the beginning a whitish puriform fluid, and of variable size, from a pin-head to a silver quarter-dollar; *vesicles*, containing a clear yellowish fluid, likewise of variable size; *blebs*, varying in size from a split pea to a half-cherry; and, lastly, *papulo-vesicles*, acuminate in form, and exuding a small amount of a serous, gluey, gummy product. The "watery blisters," as he termed the vesicles and blebs, had, on every occasion of their appearance, been very itchy; the pustules itched but little. The vesicles and blebs grew rapidly, reaching their full size in a few days, and were accompanied by but slight inflammation about their bases; the pustules, on the other hand, were always markedly inflammatory. On each occasion of the pustular form of eruption he "felt badly," and was in poor general health. He had had but three or four "pustular attacks," the rest having all been vesicular and bullous. The disease, whatever the form of lesion, always manifested itself in attacks, which would announce themselves at intervals of weeks or months, one scarcely subsiding before another would appear. He does not remember that any of the attacks were preceded by chills or fever. The seasons seemed to exert no influence on the course of the disease. He noticed that frequently the lesions inclined to come out in the form of groups or clusters, four or five appearing within a radius of an inch or two, and often coalescing. The regions invaded have been the same as in the beginning—the face, neck, elbows, knees, sacral region, and buttocks being the favorite localities. The genitalia, hands, and feet have generally been free; the palms and soles have always escaped.

His condition when I saw him in January, 1879, was very similar to that recorded as existing when I first observed the case in 1874, and therefore need not be described in detail; so much did his condition resemble the former state, as regards the general character and distribution of the eruption, that it seemed as though the very same lesions were present. The pustules were the only lesions. They were of all sizes, most of them being as large as dimes and quarter-dollars; rounded or irregular in shape; crusted with yellowish-brown crusts; flat; here and there clustered or about coalescing; in all stages of development, and surrounded by highly inflamed, extended, bright-red areolae. They, moreover, possessed the characteristic before noted of extending around the periphery and just beyond the line of the central crusting. The patient was ordered wine of iron, with three-minim doses of liquor potassii arsenitis thrice daily. With the view of observing the course of the lesions, local treatment was withheld.

March 11, 1879.—The case has been under constant observation since the previous note, six weeks ago, during which time the disease has behaved much as it did on the first occasion I had of studying it. The lesions have pursued a rather slow course, considering their highly inflammatory nature, an average pustule lasting, from the beginning until the crust dropped off, from two to three weeks. Many new lesions, all strictly pustular in character, have from time to time appeared, as a rule, in crops, while the older ones have, at the end of a variable period,

disappeared, leaving persistent dark-red, brownish, pigmented marks. No scars remain. One peculiarity of mature pustules has not been referred to, namely, the tendency for the inflamed skin around the crust to pucker, giving the skin a wrinkled, drawn-up, glistening appearance. The disposition of the lesions to group has always been present, though at times only to a slight extent. It has not, however, been observed with all of the lesions, many appearing singly. As they increased in size there would generally be noted a number of discrete or confluent small, pin-head sized, flat pustules immediately around the circumference of the original lesion in the form of a ring. This feature varied, being much more pronounced in some cases than in others, and at times was wanting. The pustules, however, seemed to grow in this manner, a new ring of minute pustular points springing up every few days around the crust until the lesion reached its determinate size. The crusts were adherent; upon lifting them up, a superficial, reddish excoriation, covered with a slight puriform fluid—as in the case of ecthyma—presented itself. Little or no bleeding occurred. Itching has not been severe, but the lesions have "felt sore."

Three nights ago he was attacked with violent itching of the general surface, accompanied with an efflorescence which he describes as having been identical with certain attacks before experienced on several occasions, and which was plainly urticarial in nature. It began, while in bed, upon the arms, but soon extended itself over the whole surface except the hands and feet, the backs, as well as the palms and soles, remaining free. The eruption was *erythematous* and very red, and exceedingly itchy; so much so that he was kept awake all night. The next day the eruption disappeared, but he felt poorly and complained of loss of appetite and malaise. Last night, just after going to bed, it suddenly reappeared in the same manner as two days before. The attack was preceded by chilliness and malaise; later he perspired profusely. To-day he feels better, and the rash is leaving the surface. The skin, however, is still red; rough in patches; slightly papular and vesicular, and has the appearance on the arms of an erythema multiforme in the stage of declination; scratch-marks abound. It seems as though the attack had been abortive, the development of the papular and vesicular lesions having been checked early in their course.

16th.—During the past five days the eruption has been disappearing, with slight desquamation and considerable pigmentation, some of the patches on the trunk somewhat resembling irritated tinea versicolor. Within the week a half-dozen, large and small, pustules have come on the arms and buttocks, identical with those which have been described.

25th.—A number of variously sized pustules have been appearing here and there over the surface, in particular on the neck, around the navel, on the lumbar and sacral regions, and over the buttocks and thighs. They all incline to dry and crust in the center, sometimes as a depressed, cup-shaped crust, and to spread on the circumference, thus extending their size. Their edges are more or less "puckered" and slightly raised; their areolæ large, dark-red in color, and contracted, presenting a somewhat stellate, radiate appearance. There is now but little itching. He is still taking four minims of the liquor potassii arsenitis, which he has been using for a month, but with no benefit.

June 20th.—Has been annoyed greatly with disease since the last note, which has manifested itself, as heretofore, in the form of distinct outbreaks appearing at irregular intervals. But at no time within the past three months has he been entirely free. The lesions at present are *vesicular* and *bullous*, from the size of large pin-heads to coffee-grains, and are scattered especially over face, arms, and forearms, and over the region of the spinal column. They are accompanied with intolerable itching. Dur-

ing the last six weeks he has been using half-ounce doses of linseed-meal, with the view of improving the nutrition, but without benefit.

June 1, 1884.—Five years have elapsed since the last note, during which period I have not seen the patient until a few days ago. He is still suffering with the disease, having never obtained any relief from the manifold treatment to which he has been subjected. For the past three or four years the attacks have been lighter than formerly, and the lesions for the most part vesicular in character. At the present time the face, neck, and trunk are the seat of small, ill-defined vesicles and papulo-vesicles, accompanied, as before, with itching. The general health is improved, and he is able, when not suffering from an attack, to attend to his daily duties.

I shall make no comments upon the case except to say that it illustrates a typical expression of this peculiar disease, characterized as it is by rare multiformity. It shows almost all of the lesions to which I have called attention in describing the disease,* and upon which its several varieties have been based. In conclusion, I may add that the affection is usually well defined, having distinctive features which enable it to be readily recognized, although it may be confounded with eczema, herpes, and pemphigus, according to the lesions at hand.

THE NEW SPECIFIC FOR RHEUMATISM.

BEING AN ANALYSIS OF ONE HUNDRED AND EIGHTEEN CASES TREATED WITH THE OIL OF GAULTHERIA.*

By H. H. SEELYE, A. M., M. D., AMHERST, MASS.,
LATE HOUSE PHYSICIAN IN BELLEVUE HOSPITAL.

(Concluded from page 510.)

The tables given below will show, in a condensed and comprehensive form, the comparative advantages of the two contrasted methods of treatment, and deductions as to their relative value can then easily be drawn:

TABLE I.

	Ol. Gaulth.	Sal. Acid.
Number cured.....	76	72
Number improved.....	8	16
Number of deaths.....	6	2
Total.....	90	90

TABLE II.

NUMBER DISCHARGED	CURED.			IMPROVED.			DIED.		
	O.	G.	S.	O.	G.	S.	O.	G.	S.
Between 1 and 7 days.....	34	36	2	6	3	0			
Between 7 and 14 days.....	21	13	1	4	3	1			
Between 14 and 21 days.....	10	7	3	4	0	0			
Between 21 and 30 days.....	7	7	1	1	0	1			
Between 30 and 45 days.....	4	5	1	1	0	0			
Between 45 and 90 days.....	0	4	0	0	0	0			
Between 1 and 90 days.....	76	72	8	16	6	2			

TABLE III.

76 patients treated by oleum gaultheriæ were discharged	
cured within a total of.....	877 days.

* "Jour. of the Amer. Med. Assoc.," August 30, 1884; also, "Amer. Jour. of the Med. Sci.," October, 1884.

72 treated by salicylic acid were discharged cured within a total of	1,040 days.
The average time under observation of each patient cured by oleum gaultheria was about.....	11½ "
The average time under observation of each patient cured by salicylic acid was about.....	14½ "

TABLE IV.

The average number of days of sickness before admission, of each of 60 patients treated by oil of gaultheria, was about.....	12 days.
The average number of days each of the same 60 remained in the hospital was.....	10½ "
The average total duration of the disease with each of the 60 discharged cured was.....	22½ "

TABLE V.

Number of patients with cardiac complications treated by oil of gaultheria and cured of the rheumatism.....	11
Number improved.....	2
Number that died.....	1
Total number with cardiac complications.....	14

TABLE VI.

	Improved by Ol. Gaul.
Number of cases of chronic rheumatism.....	16
" " " " rheumatoid arthritis.....	3
" " " " gonorrheal rheumatism.....	3
" " " " gouty rheumatism.....	2
" " " " coxalgia.....	2
" " " " syphilitic rheumatism.....	1
" " " " muscular rheumatism.....	1
Total number of cases of chronic forms of rheumatism.....	28

On looking over these tabulated statistics we see by the first table that, out of ninety similar cases treated by each method, the oil of gaultheria has the advantage of four more cases cured by it than by the salicylic-acid treatment, and also in the fact that eight more cases refused to yield to the acid than to the oil, and the patients were necessarily discharged only improved. But the gaultheria apparently loses all this advantage by a record of three times as many deaths as could be attributed to the salicylates. Yet this disadvantage may actually be more apparent than real, because all of the six patients who died had unmistakable symptoms of acute alcoholism, which symptoms there is no reason to believe were induced by the oil of wintergreen. Besides, a corresponding number may have died in the same way under the other plan of treatment, and have escaped the writer's notice, possibly by their having been classified in the indices of the history-books under the heading of "acute alcoholism."

The second table shows more clearly wherein lies the chief superiority of the oil of gaultheria over the salicylic acid, and that is in the greater number of cases cured by it in a moderate length of time. The acid seems to act with just about the same promptness as the oil in a certain number of cases which are readily amenable to treatment, but it is in speedily subduing those more obstinate cases which resist the first assaults of the remedy that the oil has the advantage. Its persistent and oft-repeated attacks at length seem to weary out the disease and to destroy the morbid elements in the system on which it thrives, until at length the malady is completely overcome. The salicylic acid, on the other hand, if it fails to overpower the disease at once,

either yields up the field entirely or its administration must be long persisted in before its efforts are crowned with success. Out of the ninety cases recorded as cured in the table, sixty-five yielded within three weeks to the oil, while only fifty-six succumbed to the acid; and nine cases treated by the latter drug ran along for over a month, to four treated by the former.

The real superiority of the wintergreen over the salicylates is again seen in the third table, where is shown the average number of days each patient who was cured remained under observation in the hospital. It was eleven and a half days for those treated by the oil to fourteen and a half days for those who took the acid—an advantage of three days for the gaultheria.

It would be unjust to suppose that these tables represent the actual duration of the disease after the patients entered the hospital, for in the case of those treated by the gaultheria, and probably also with those treated by the salicylates, it was the custom to keep them under observation for at least two or three days after all the pains and other active symptoms had disappeared, in order to build up the debilitated constitution by tonics and nourishment, as well as to guard against an early relapse. On this account alone an average reduction of about two days and a half from the time of stay in the hospital may safely be made, in order to determine the actual duration of the disease after the treatment by either method was begun. This would leave the average length of the gaultheria treatment as nine days, and the salicylate as twelve. But a still further deduction ought to be made from the time of the gaultheria treatment by reason of delays caused by the substitution of an inferior article, either the oil of birch, or a diluted oil of wintergreen,* during four or five out of the eighteen months of experimentation. With these considerations it is fair to suppose that, under favorable conditions, the mean duration of the disease under the treatment by the oil of wintergreen would not exceed one week.

Again, in the matter of the greater infrequency of relapses the new treatment seems to surpass the old, for, in looking over the histories of the patients treated by the salicylates, it was very remarkable how much more frequent such slight and brief recurrences of the attacks were than was accustomed to be seen in our wards where the gaultheria was used. Under both treatments, however, these mild relapses seemed to yield promptly to a renewal or an increase of the medicine.

In respect to the relative frequency of cardiac complications developing in the wards, there was no noticeable difference, and, besides, the records on this point, under both plans of treatment, were too indefinite and inaccurate to be of much practical value.

As regards the whole duration of the disease as influenced by the oil of gaultheria, some information may be derived from the fourth table, which gives the length of time it had already existed before admission to the hospital in the only sixty cases in which this point was noted in the histories, it being, on an average, about twelve days; and also

* Some of the oil of wintergreen analyzed proved to contain about 25 per cent. of alcohol.

the length of time these same sixty cases remained under observation thereafter, namely, about ten days and a half. This gives an average duration of the disease as twenty-two days and a half, less about two days' and a half retention in the ward after convalescence was complete, making about twenty days as the mean duration of the disease. In this connection some figures collected from Dr. Austin Flint's article on acute articular rheumatism will be of interest. Of thirteen cases noted by him in 1862, in which all medicinal treatment was refrained from, the average duration was about twenty-six days. The mean duration of forty-one similarly treated cases reported by Dr. Sutton in 1865 was, twenty-seven days after admission to Guy's Hospital.* The present methods of treatment, therefore, have a markedly perceptible influence in shortening the duration of the disease.

Our experience corresponded with that of Dr. Flint, Dr. Sutton, and others, in finding the disease more obstinate and of longer duration, though of less frequent occurrence, in females than in males.

The only thing to add in reference to the different classes of chronic cases recorded in the sixth table is that, in looking over the histories of patients treated by the salicylates, it was noticeable that the cases indexed as chronic, and so forth, were proportionately much more numerous than those which had come under our observation. This difference in the relative proportion of acute and chronic cases admitted to the wards where a different course of treatment was pursued could not fail to awaken the suspicion that many obstinate cases, which would have yielded promptly to one class of treatment, were, on account of the failure of the other method, so prolonged in duration that what was perhaps on admission considered an acute attack was at length classed and indexed as a chronic disease.

In connection with the consideration of this drug in its relations to acute rheumatism, it will be appropriate here to record the results of our limited experience in its local use. In a somewhat recent issue of one of our prominent medical journals it was stated that an emulsion, composed of equal parts of the oil of wintergreen and olive-oil, or the ordinary soap-liniment of the Pharmacopœia, was an excellent topical anodyne application to inflamed and painful rheumatic joints. Acting on this suggestion, it was tried in a considerable number of cases, and nearly always with excellent results in giving prompt relief from the acute suffering. Of course, this was only used as a palliative and temporary measure while waiting for the constitutional remedy to impress itself upon the system.

Aside from the employment of the oil of wintergreen as an anti-rheumatic, the writer also wishes here to make a brief statement of the results of his experience in the use of the same drug as a remedy for malarial fever. The trial of it in

this disease was suggested by the similarity of its chemical composition to that of quinine, and also by the close identity of the physiological symptoms produced by an excessive administration of either drug. In the few cases of daily repeated chills in which it was tried, it seemed to speedily check the return of the paroxysms, there usually being none, or but one chill recurring after its administration in the usual dose was begun. Still, in some cases after the withdrawal of the drug there was an early return of the paroxysms.

In summing up the results of our experiments with the oil of gaultheria, a brief recapitulation of the most important points brought out will recall more clearly to mind the advantages of this drug as an anti-rheumatic agent. We have found that it has all the valuable properties of salicylic acid, to which it is closely allied. Its action is more prompt and efficient in obstinate cases. It has a more agreeable taste. Relapses under its use are less frequent. The unpleasant effects of over-dosing are no greater, and it is less depressing. Cardiac complications are no more frequent. It is important not to substitute the oil of birch or a diluted article for it. Large and frequent doses are necessary to get the best effects. It is an efficient palliative remedy in chronic and irregular forms of rheumatism. It is a local anodyne to inflamed joints.

It only remains now for us to add the reason why in this article the oil of gaultheria has been contrasted in its therapeutical properties with salicylic acid. This is because the salicylic treatment of rheumatism is the one most popular at the present day, and has given more satisfactory results in the acute form of the disease than any other remedy heretofore discovered. If, therefore, it can be shown that a more recent plan of treatment, carried out under similar conditions and in the same climate, surpasses in its results the one up to the present time considered the best, it is unnecessary to discuss its advantages over all inferior remedies. So, as Dr. MacLagan, in 1876, announced that he had discovered in salicin a specific for acute articular rheumatism, the foregoing facts and statistics have here been presented in order to substantiate the statement that we now have in the oil of gaultheria a remedy still more worthy to be called a specific, for by its aid we can speedily cure nearly eighty-five per cent. of all cases of this disease.

A CASE OF PENETRATING FRACTURE OF THE CRANIUM; RECOVERY.

By G. E. BUSHNELL, M. D.,

ASSISTANT SURGEON, UNITED STATES ARMY.

W. L., a miner, forty-nine years of age, was injured by the explosion of a blast, January 30, 1882, a fragment of rock striking his forehead and fracturing the skull. He was stunned by the blow, but before help arrived recovered his senses sufficiently to notice that the ground about him was bespattered with brains. With assistance he walked to a house distant about twenty rods. The writer saw him two hours after the accident. The patient was partially conscious. There was a perforation of the skull at the right frontal eminence about an inch in diameter, through which a large mass of brains protruded, extending to the eyebrow. This protrusion was so extensive that the inner surface

* Within the past twelve years, the average number of days one hundred and thirteen patients remained in Roosevelt Hospital under the salicylate treatment before they were discharged cured was, according to recently published statistics of Dr. Charles H. May, about twenty-five, while the whole duration of the disease averaged forty-two days. ▲Against these figures we show a stay of only nine days in the hospital, and a total duration of the disease as about twenty days.

of the cranial vault was visible for a distance of at least two inches. No foreign bodies could be discovered within the cranium, except a small piece of bone. Some strips of lacerated brain-substance, weighing about two drachms, were cut off, and the remainder of the prolapsed portion was cautiously cleansed with carbolized water and returned, as far as possible, to the cranial cavity. The brain, however, remained on a level with the skin of the forehead until healing was far advanced. The wound having been bandaged, the patient was placed upon the right side to insure drainage of the wound, and the attendants were directed to enforce that position. During the first few days after the injury the patient lay in a state of semi-consciousness, answering when spoken to, but not intelligently. The discharge from the wound was abundant, consisting apparently of broken-down brain-tissue. Small pieces of bone were removed on several occasions. Black specks began to appear in the discharge. These rapidly increased in number, and continued for several weeks to be profuse enough to blacken the dressings.

Fortunately, the explanation of this, at first sight, rather puzzling phenomenon was furnished by the case of the other workman present in the shaft at the time of the explosion. This man escaped serious injury, but his skin was riddled by small fragments of rock, many of which penetrated to the depth of an inch. On examination, two hours after the injury, the probe failed to detect the presence of a foreign body in any of these wounds, but on the following day masses of mud were readily squeezed from them all. The stone which inflicted the wounds was found to be a hardened clay, which, although of the consistence of ordinary rock when first mined, on exposure to air and moisture rapidly softened into an impalpable mud.

Neither the character of the injury nor the patient's symptoms excited at first any suspicion of the existence of compression. But about the eighth day the breathing changed in character, growing gradually stertorous, and there was incontinence of urine and feces. A thorough exploration of the wound was decided upon. The operation was performed on February 10th, with the assistance of Dr. J. C. McGuire, Acting Assistant Surgeon, U. S. Army. All of the edge of the cranial aperture being accessible to observation, except the inner and lower portion, which was covered by the integument, a vertical incision an inch in length was made through the soft parts at this situation. A narrow strip of bone at the inner edge of the fractured orifice was found to be fissured and slightly depressed. An attempt to elevate the depressed bone was made, using the outer and upper edge of the perforation as a fulcrum. Slight force had been exerted, when the edge of bone which supported the elevator suddenly sank, and an elevation appeared two inches posteriorly and externally, showing the existence of a large fragment which had hitherto escaped displacement. This was reduced so easily and perfectly that it was thought best not to remove it. A cut with a Hey's saw was then made through the outer table along the line of the fissure, after which the depressed bone was readily elevated. Two pieces of bone were then discovered well to the inner side of the perforation, which had been wedged in beneath the depressed bone. These were removed, and with them a bit of black felt from the patient's hat. After this operation the patient became conscious, and convalesced without an unfavorable symptom. He began to do light work in April. At that time his friends noticed that he was very absent-minded, but his condition gradually improved in this respect. At present the cicatrix does not pulsate, and the cranial aperture is occluded by a firm septum nearly as hard as the surrounding bone. The patient is able to do with ease the heavy work which his occupation makes necessary, and, except for an occasional headache, his health is very good.

With regard to his mental condition, so far as can be judged from infrequent personal observations and from the statements of his friends, it has not been permanently impaired by the extensive loss of brain-substance.

Aside from the possibly unique mode of elimination of the foreign body from the cranial cavity, this case is worthy of note on account of the rarity of recovery from extensive brain-lesions in persons advanced in years.

FORT ELLIS, M. T.

NOTE ON THE TREATMENT OF PUERPERAL ECLAMPSIA.

By JAMES F. SULLIVAN, M.D.,

SAN FRANCISCO.

I HAVE just been reading in the *Journal* of August 16th some very interesting accounts of cases of puerperal convulsions, reported at a meeting of the New York Obstetrical Society, and venture to give the outline of a course of treatment which has proved so eminently satisfactory in my last six cases that I now no longer dread that frightful complication of labor.

In an unusually large obstetrical practice of about thirty-six hundred cases, I have met with thirty-three cases of eclampsia, exclusive of mild cases of a purely hysterical character. Of course, in cases complicated with uræmic poisoning from organic disease of the kidneys (with partial or almost total suppression of urine) no set plan of treatment can be laid down, but we know that the urine may be heavily charged with albumin toward the end of pregnancy without the existence of organic disease.

The first indications of treatment are to relieve the bowels by free injections and three drops of croton-oil on the tongue, together with other purgatives as required.

If, however, one or several convulsions have already occurred, I inject hypodermically, without delay, twenty drops of fluid extract of veratrum viride and half a grain of morphine.

If the pulse is full and tense, free bleeding from both arms is a most important measure.

These means having been resorted to, the next convulsion is delayed much longer than usual, and is far less severe. After an interval of fifteen minutes, if the pulse has not yielded in force and frequency, ten drops more of veratrum viride are to be injected, and so on every fifteen minutes *till the pulse does yield*, and then the convulsions have always ceased, in my experience, without any subsequent ill effects to mother or child.

The action of veratrum viride in these cases is simply a mechanical proposition—reducing the force of the circulation, thereby relieving the brain pressure—and if the case has been seen in the beginning, before effusion has taken place, recovery is almost certain. Nor do I consider forced delivery a wise or necessary measure unless the os is dilated or easily dilatable. If the os is rigid, or if, as frequently happens, no labor-pains have occurred, I believe that no effort should be made to hasten delivery. If the term of pregnancy has fully expired, the morphine and veratrum will relax the os, and labor will generally progress naturally

without a return of the convulsions. In one of my cases, in which the woman, a primipara, was in convulsions for three hours and unconscious for twenty-four, labor did not occur for a week, and then came on very favorably, with no return of the convulsions, and terminated naturally with the birth of a healthy child.

NOTE.—These doses of veratrum viride may appear large, but violent diseases require heroic treatment. The last edition of the "United States Dispensatory" speaks of veratrum viride as "a prompt, thoroughly efficient, and at the same time very safe remedy—very safe, since it is almost incapable of producing death in the robust adult unless used with great recklessness and in repeated doses."

A CASE OF EXCISION OF THE SHOULDER JOINT FOR DISEASE FOLLOWING INJURY.

By W. R. BARTLETT, M. D.,
NEW HAVEN, CONN.

In June, 1878, I was called in consultation by Dr. S. D. Gilbert, of this city, to see Arnold N. Spencer, aged about eighteen, from the country, of a scrofulous temperament, who was suffering from the effects of a bruise in the vicinity of the shoulder joint, caused by being run over by a wagon about three months previously. On examination, there was found a sinus situated at the lower border of the anterior fibers of the deltoid. On probing, the bone was found to be extensively diseased. It was determined to make an exploratory incision along the course of the sinus, and, if the necrosis proved to be of limited extent and superficial, to remove the diseased portion; but, if the whole bone was involved, as seemed probable, to excise the joint. The patient having been etherized, I proceeded to do this, the incision being made at the seat of the sinus about three inches in length, upward and downward, between the two heads of the biceps. It was soon found that excision would be necessary, as the whole bone was much softened and the joint evidently diseased. About three inches of the upper portion of the shaft of the bone, including the head, were removed, the bone having been sawn through with a chain saw at the lower limit of disease. The bone was removed in small pieces, as I was able to detach them with a gouge and elevator, that portion of the head above the anatomical neck being removed in one piece. The operation was performed without the division of an artery and with but little injury to muscle, as much of the periosteum being preserved as was possible, which was limited, owing to the softened condition of the bone. Dr. Gilbert attended to the case subsequently, the principal dressing being daily syringing of the wound with a solution of carbolic acid in water, the limb being kept in an easy position upon a pillow, the wound filling by granulation. The patient did well, and, as soon as he was able to be about, the arm was placed in a sling. In about two months the wound was entirely healed. The result of the operation has been most excellent, at the present time, the patient having a strong and useful arm, with almost complete movement of the arm overhead as well as below, and he is able to do an ordinary day's work with it. There is about two inches and a half of shortening, with some production of new bone. The result obtained, and especially the preservation of upward movement, I believe to be largely due to the careful manner in which the operation was performed, and the preservation of the deltoid.

The fact that excision for disease is comparatively rare (Ashurst, for instance, having met with only one case*)

* See "International Encyclopædia of Surgery," vol. iv, p. 478.

and the unusually good result obtained appear to me to make the case worthy of record, which I now detail after my first inspection of the result. Since the operation, the young man has suffered from abscesses in the groin and anal region, through which several small pieces of bone have escaped while under treatment by Dr. Gilbert, and at the New Haven Hospital, thus indicating involvement of the pelvic bones. At the present time there are no sinuses open and the patient is in fair health, though of a phthisical tendency, having had several hæmorrhages.

Book Notices.

BOOKS AND PAMPHLETS RECEIVED.

Micro-organisms and Disease. An Introduction into the Study of Specific Micro-organisms. By E. Klein, M. D., F. R. S., Joint Lecturer on General Anatomy and Physiology in the Medical School of St. Bartholomew's Hospital, London. With 108 Engravings. London: Macmillan & Co., 1884. Pp. xii-195. [Price, \$1.]

The Elements of Physiological Physics: an Outline of the Elementary Facts, Principles, and Methods of Physics; and their Applications in Physiology. By J. McGregor-Robertson, M. A., M. B., C. M., Muirhead Demonstrator of Physiology, etc., in the University of Glasgow. Illustrated with 219 Engravings on Wood. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xii-528.

The Treatment of Uterine Displacements, including Prolapsus, Anteversion, Retroversion, Antelexion, and Retroflexion. By W. Eggert, M. D. Second Edition, Illustrated. Chicago: Duncan Brothers, 1884. Pp. 136.

Dental Caries: a Critical Summary; and the Prevention of Dental Caries. By Henry Sewill, M. R. C. S. and L. D. S. Eng. London: Baillière, Tindall & Cox, 1884. Pp. 66.

Practical Recommendations for the Exclusion and Prevention of Asiatic Cholera in North America. An Address delivered at the Opening of the National Conference of State Boards of Health, St. Louis, October 13, 1884. By John H. Rauch, M. D., Secretary, Illinois State Board of Health.

Contributions to the Anatomy and Pathology of the Nervous System, based on Researches conducted in the Private Laboratory of E. C. Spitzka, M. D. Series III, No. 3. Singular Case of Vertebral Disease, etc. By Richard Mollenhauer, M. D., Physician to the Northeastern Dispensary.

Abstracts from Papers on Hydatid Disease, etc. By James W. Barrett, M. B., M. R. C. S., etc., London. London: Wyman & Sons, 1884.

De las Cataratas Hereditarias y de su Trasmision principalmente á los Individuos de Sexo Igual al del Paciente Originario. Por el Dr. D. Luis Carreras-Aragó, Profesor Libre de Oftalmología, etc. Barcelona: E. Ullastres, 1884.

Club-Foot. Is Excision of the Tarsus necessary in Children? By De Forest Willard, M. D., Philadelphia. [Extracted from the "Transactions of the Medical Society of the State of Pennsylvania."]

On Oxygen as a Remedial Agent. By Samuel S. Wallian, M. D. [Reprint from the "Medical Record."]

An Aid to Materia Medica. By Robert H. M. Dawbarn, M. D., late Resident Physician to the Nursery and Child's Hospital. New York: J. H. Vail & Co., 1884. Pp. 86. [Interleaved.]

NEW YORK, SATURDAY, NOVEMBER 15, 1884.

THE PROBLEMS OF THE CHOLERA.

It does not seem at all likely that the problems presented by the cholera will soon be solved, either from the sanitarian's point of view or from that of the practitioner of medicine. Those problems are engaging the attention of the profession, as well as that of the general public, more and more; and in this country, far removed as it is from the scenes of the present prevalence of the disease, the same thing is true, as is shown by the prominence given to the subject at the two great sanitary meetings lately held in St. Louis, the National Conference of State Boards of Health and the annual meeting of the American Public Health Association, by the numerous and carefully considered addresses and circulars relating to it that have emanated from two or three of our western State boards of health (either from those boards in their corporate capacity or from the distinguished sanitarians who are connected with them), and by the fact that two very remarkable papers on cholera, dealing with it chiefly from the standpoint of State medicine, have recently been read before two of our New York medical societies by gentlemen to whom the profession always listens with the greatest attention, and who never write papers for the purpose of bringing themselves forward, but solely in the interest of science and humanity. We refer to Dr. Flint's paper, read before the New York County Medical Association, which was published in our issue of October 25th, and Dr. Hamilton's paper, read before the Academy of Medicine last week, the full text of which we give in this number of the journal.

The germ theory of the disease excites, of course, the liveliest scientific interest, and it is practically with that theory that both Dr. Flint and Dr. Hamilton deal. Each of these gentlemen has given a remarkably fair and clear statement of Koch's bacillus doctrine, but neither of them regards it as proved. Further experience, further clinical observation, a more copious collation and a closer digest of facts bearing upon the natural history of the disease, are necessary to the solution of the question. The first step in such an inquiry, it seems to us, is to distinguish between what is essential to the germ theory and what are the comparatively immaterial details enunciated by Koch. It is quite probable that by a plan of exclusion those of the latter that are untenable may very speedily be sifted out. To begin with, the facts at present known to us seem to warrant a flat denial that so short-lived an organism as Koch makes his bacillus out to be, at least as regards its morbid power, can be the sole cause of the transportation of the disease to the vast distances that it has been known to travel over with little, if any, manifestation of its disease-producing power on the way. "In 1873, for example," says Dr. J. H.

Rauch, the accomplished secretary of the Illinois State Board of Health, in his address before the National Conference of State Boards of Health, "there were outbreaks of epidemic cholera at Carthage, Ohio, Kandiyohi County, Minnesota, and Yankton, Dakota, caused by cholera poison packed up in the household effects of emigrants in Holland, Sweden, and Russia, respectively; these emigrants sailed from healthy ports, in healthy vessels, and were subjected to the usual sanitary requirements of the period. They passed through New York and all the intermediate territory without injury to the public health. But when their infected goods were unpacked in the interior of the continent they liberated the poison which gave rise to the local outbreaks." Who can bear such facts in mind—and they are by no means exceptional—and yet cling to the idea that a cryptogam that is killed by desiccation, that under circumstances most favorable to its death-dealing career goes through the allotted period of its evolution within a few days at most, and that is incapable of passing, like the small-pox germ, into a "resting stage," can have been the real cause of such outbreaks? Either Koch's bacillus is not the cause of cholera, or else its life-history has not been correctly described by Koch.

The reports that the bacillus has been swallowed with impunity prove nothing, unless we decline to accept the doctrine, held by Koch, that a disordered state of the alimentary canal is a prerequisite to the production of the effect. That we must decline to accept that doctrine seems to us very probable. We are quite willing to admit that there may be some truth in the popular idea that a perfectly healthy system often successfully opposes the pathogenetic action of a contagium, but that is a very different thing from admitting that an unhealthy state of the system is really necessary to the action of the contagium. Even this may be true with regard to some of the infectious diseases, diphtheria for example, although we do not wish to be understood as making any statement to that effect; but it seems to us in the highest degree absurd to inculcate such a doctrine with regard to cholera, a disease which runs its course quite as destructively among those who are in perfect health as among others, or at least with so little difference that it is not worth mentioning.

Such considerations as these do not disprove or even materially weaken the germ theory properly defined; they do not even deal a blow at the comma bacillus theory; but they should, we think, compel a narrowing of the theory down to its essentials, and serve to show what abundant need there is that experimental investigations should be seasoned with the grain of salt that common sense may be able to furnish, and submitted to a final comparison with deductions that may be as fairly drawn from ordinary observation as from technical research. Truth must be consistent in all its parts.

Admitting, with Dr. Hamilton, that thus far clinical observation has taught us more about cholera than the microscope, it must still be confessed that the remedial art is well-nigh powerless for its cure. Notwithstanding the great usefulness of opium in the premonitory stage, patients do pass on to the algid stage and die in great numbers. The question of prevention, then, remains uppermost, and the means of prevention are

quarantine and local sanitation—neither the one nor the other alone, but the two together. In the presence of such a danger as is involved in an invasion of the cholera, let there be no petty wrangling as to which of these two measures is to be relied upon, but let us avail ourselves to the utmost of both. Believing that this is the true course to pursue, we consider it an occasion for congratulation that the inland boards of health in general seem to sustain it. We may trust to them for local sanitation, and we may trust to the Marine-Hospital Service to enforce an efficient quarantine.

LISTER ON CORROSIVE SUBLIMATE.

As one of the London medical journals remarks, Sir Joseph Lister's addresses are always "drawing." This was notably the case with his recent paper read before the Medical Society of London. The importance of the subject, as well as the speaker's prominent connection with it, was enough to win for him a large and appreciative audience.

Apart from the scientific value of his statements with regard to the antiseptic properties of corrosive sublimate, and especially his interesting experiments with the albuminate, or, rather, mixture of the bichloride of mercury and blood-serum (1 part to 100), there remains a higher lesson. We have seen the rise and spread of his system, have heard Lister overwhelmed with laudation which would have long ago turned the brain of a smaller man, and convinced him of his own infallibility, but he, the great teacher, whose words are received with reverence by thousands of disciples, does not hesitate to acknowledge his failures as promptly and openly as his successes.

"When, in an address delivered at the opening meeting of last session, I expressed myself in what some of my hearers regarded as terms of overweening confidence in the trustworthiness of antiseptic treatment, I little thought that a year later I should have to tell you of failures on my own part."

It is such confessions as this that strengthen our admiration of the man, while they increase our respect for the teacher.

Crowned with honors, all of which have been justly earned, here is one who is not done with learning, even from his own mistakes. Such a man can not be narrow, he can not be an unsafe leader. Whatever may be said against "Listerism," the opponents of that system should not forget that its author has taken a long stride ahead since he promulgated his original doctrines.

MINOR PARAGRAPHS.

AN INTERESTING OUTBREAK OF "HORSE-POX."

At a recent meeting of the French *Académie de médecine*, as we learn from the "Gazette hebdomadaire de médecine et de chirurgie," M. Blachez related the particulars of an outbreak of casual "horse-pox" among the she-asses used for giving suck to the inmates of a nursery where only syphilitic children, or children supposed to be syphilitic, are received. One of the children was found to have a large ulcer on the lower lip, with considerable swelling of the part, and at the same time a deep, indurated, discharging excoriation was found on the teat of an ass that had suckled the child. It was ascertained that, a fortnight before, the same ass had suckled a child with a specific ulcer of the tongue. It was hastily inferred that this child had

infected the ass and (mediately) the first child with syphilis, but Professor Bouley, the veterinarian, was asked to investigate the case, and he decided that the disease was really "horse-pox," originating from a vaccinated child. The disease spread among the asses of the establishment, and "cow-pox" was produced in two cows by inoculation from one of the asses.

A NOVEL REMEDY FOR BALDNESS.

UNDER the caption "*Le vaccin pilifère*," the well-known Lyonnese syphilidologist, M. Diday, in a recent issue of "*Lyon médical*," shows either that he is ready to clutch at the veriest straw in the hope of rehabilitating his bald pate, or else that he is the most incorrigible joker in all France. The case that he makes the text for his imaginative article was that of an infant, the daughter of a physician, who was vaccinated at the middle of each thigh, in front, with cow-pox virus furnished by the city vaccine service of Lyons, in the shape of lymph on a glass plate. The local inflammation was considerable, but everything went on as was to be expected until the sixtieth day, when the scars, still red, were found to be surrounded, each one of them, with a fine growth of red hair—*roux de vache*, as he is particular to mention. What an opportunity for the *ad captandum vulgus* would an occurrence of this sort have furnished to the caricaturists who, eighty-five years ago or so, took such delight in picturing the bovine characteristics which, they averred, were sure to fasten upon the unfortunate subjects of "the new inoculation!"

But the point of the story is yet to come. The child's father called M. Diday's attention to three or four hairs, evidently cow's hairs—"petits, mais très visibles à l'œil nu"—on the glass plate. Straightway the narrator of this stirring tale began to build castles. The hair, or at least its germ, had doubtless been inoculated or transplanted, he concluded, and what a capital opportunity there was of regaining his own lost locks! He besought the child's father to vaccinate him on the top of the head with the same virus, but we grieve to relate that his request was not complied with, and that, for the present at least, the world has lost the revelation that might otherwise have been given to it.

AN ABBOT AND HIS ERRING PARISHIONER.

"*LYON MÉDICAL*," quotes the following edifying tale from the "*Journal de médecine de Bordeaux*." The ecclesiastics, as is well known, have fallen into the bad habit of dabbling in medicine and pharmacy, pretending to know them as well as the Gospels. An abbot named X. was lately the victim of this unfortunate propensity. One of his female parishioners, finding herself in great suffering, consulted a physician in the neighborhood, who regretted to find that she had a well-marked gonorrhoea, and accordingly prescribed copaiba and cubeb in liberal doses. Before taking these poisons, the fair one thought it prudent to ask the curate what he thought of them. The latter looked at the prescription, and exclaimed, "Balsamics, those are used for the chest. Yours is weak. You can take them." And, generous to the last, he wrote these words across the prescription, "Furnish at my personal expense." The story goes on to say that an occasional sly laugh is still called up at the apothecary's by a perusal of the indorsement on that prescription.

REMBRANDT'S TULPIUS AND HAMMAN'S VESALIUS.

WE have received from the Berlin publishing house of Herr E. H. Schroeder a beautiful lithographic reproduction of each of these famous paintings, commonly known as "Andreas Vesalius at the Dissecting-Table" and "La leçon d'anatomie." In

the form of inferior copies, whether in lithography or as the thrice-accurSED "chromo," these pictures are tolerably well known to the medical profession in this country, but these lithographs, by Milster and Süssnapp, respectively, ought, by their great excellence, to displace the coarser attempts we have alluded to. It may interest those of our readers who are familiar with the *leçon d'anatomie* to know that the group consists of Nicolaus Tulpius, Jacob Bloek, Hartman Hartmansz, Adriaan Slabbaan, Jacob de Witt, Mathys Kalkoen, Jacob Koolveld, and Franz van Loenen.

THE MEDICINE STAMP TAX IN GREAT BRITAIN.

From a dainty little brochure on this subject, by Mr. C. E. Meeterke (published by Wyman & Sons, London), we gather certain information in regard to the marvelous credulity of the people, who, it seems, really suppose in many instances that the Government stamp affixed to a bottle of any proprietary compound is an official guarantee of the purity of the nostrum, if not of its efficacy. In view of this state of things, we can readily understand that the Stamp Act, far from discouraging the nostrum trade, has very likely had quite the opposite effect, and we think that Mr. Meeterke has done a good deed in publishing this succinct account of the many arguments that may be brought forward to show that the true interests of the people would be served by an abrogation of the tax.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 11, 1884:

DISEASES.	Week ending Nov. 4.		Week ending Nov. 11.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	41	22	38	13
Scarlet Fever.....	33	1	46	9
Cerebro-spinal meningitis....	3	3	3	2
Measles.....	52	10	102	13
Diphtheria.....	63	36	72	38

The Cholera in Europe.—Against the continued decline of the disease in Italy, we have the unsatisfactory news of its prevalence in Paris to an extent that seems to have excited considerable alarm, although perhaps this feeling is in a great degree to be imputed to the discovery that there has been more or less of cholera in the city through the greater part of the summer, but that the fact has been withheld from the public. According to a press dispatch dated Wednesday, there were about fifty deaths a day—certainly not a large number in proportion to the population. There are contradictory reports as to the existence of the disease in Brussels and in Halle.

The Health of Michigan.—It appears by the returns made to the State Board of Health for the five weeks ending November 1st, for a copy of which we are indebted to the secretary of the board, Dr. Henry B. Baker, of Lansing, that there was an increased prevalence of influenza, quinsy, bronchitis, typhoid fever, pneumonia, typho-malarial fever, and neuralgia, while that of the diarrhoeal diseases and the strictly malarial fevers decreased.

The New York Academy of Medicine.—At the next meeting, to be held Thursday evening, November 20th, Dr. V. P. Gibney will read a paper on "The Surgical Management of Rachitic Deformities of the Lower Extremities." Dr. Gibney invites discussion on one or more of the following points: I. Cases that can safely be left to Nature. II. Cases for medica-

tion and hygiene. III. Manual force and retentive splints. IV. Apparatus (cases suitable for it; the best form; results). V. Osteoclasia (the selection of cases; the selection of an instrument). VI. Osteotomy (its applicability; accidents; how the best results are secured).

The West Virginia Medical Practice Act.—We are indebted to a correspondent for the text of Judge Green's opinion, to which we alluded last week, establishing the constitutionality of the act, and we find it an exceedingly satisfactory document. It is the impression of those who have followed the trial which has led to this decision that the opinion places the employment of a physician on higher ground than that of a lawyer, and plainly shows the necessity of statutes to regulate the practice of medicine and surgery. It is thought also that it will accomplish much good by encouraging higher medical education and pronouncing authoritatively against quackery and ignorance.

The Bridgeport Hospital and the Fairfield County, Conn., Medical Society.—On Tuesday the new hospital for the city of Bridgeport was inaugurated with appropriate ceremonies, which were blended with the proceedings of the semi-annual meeting of the medical society of the county in which Bridgeport is situated. The programme, which we have already given, was carried out to the satisfaction of those in attendance, including a number of medical men invited from New York and other places in the vicinity.

The Death of Dr. Augustus H. Abernethy, of Bridgeport, Conn., is announced as having taken place on Sunday, the 9th inst., in consequence of an attack of angina pectoris. Dr. Abernethy was a graduate of the medical department of Yale College, of the class of 1864.

The Death of Dr. Neumann, professor of psychiatry at Breslau, is recorded in our Continental exchanges. He died on the 10th of October, at the age of seventy-one.

The "Annals of Surgery," which may be looked upon as in some sort the successor of the "Annals of Anatomy and Surgery," is announced as about to appear simultaneously in this country and Great Britain, under the joint editorship of Dr. L. S. Pilcher, of Brooklyn, and Mr. C. B. Keetley, of London. The list of collaborators comprises the names of a number of distinguished men in both countries, and we look to see the "Annals" a most creditable publication. It is to be a monthly, and the first number will be dated January, 1885.

Female Internes in the Paris Hospitals.—"It appears," says the "Union médicale," a journal that has vigorously opposed the admission of women to the Paris hospitals, "that, in spite of the opposition formally expressed by the majority of the hospital physicians and surgeons, in spite of the steps taken by Professor Hardy, president of the Association of Internes, and by M. Moutard-Martin and M. Nicaise, medical delegates to the 'Conseil de surveillance de l'assistance publique,' a decree of the Prefect has just authorized the admission of female *externes* to the *concours* for the coming year. The "Union médicale" bewails this blindness of the Government as a return to the dark ages.

The Woman's Hospital.—We learn that Dr. P. F. Chambers has been appointed an assistant surgeon, in place of Dr. Charles S. Ward, resigned, and that Dr. Henry C. Coe has been appointed pathologist.

The New York Hospital.—Dr. J. S. Hawley has been appointed one of the physicians for diseases of women to the Out-patient Department, succeeding Dr. E. L. Partridge, resigned.

Recent Paris Theses.—By the same journal we learn that the following *thèses de doctorat* have lately been submitted:

November 27th.—On Kola (the *Sterculia acuminata*), by M. Monnet; On Syphilitic Gummata of the Larynx, by M. Latouphis. November 30th.—The Treatment of Cancer of the Cervix Uteri during Pregnancy, Parturition, and the Puerperium, by M. Barbulée; The Physiological and Therapeutical Properties of the *Piscidia erythrina*, by M. Legoy.

A False Accusation has been brought against Dr. J. Fossagrives by a number of English newspapers, together with one homeopathic medical journal, to the effect that, having witnessed the efficacy of homeopathy and the failure of legitimate medicine in a cholera epidemic, he has become a convert to the homeopathic doctrine. He vigorously repels the slander, in a letter to the editor of the "Gazette hebdomadaire de médecine et de chirurgie," stating that he has not seen a single case of cholera during the present outbreak, and that, if he had, he would have treated the disease as any one else of common sense would treat it.

A Modification of the Rag Importation Order has been made by the Secretary of the Treasury, limiting its operation to rags from infected ports and to old rags not properly certified by a United States consular agent to have been gathered, baled, and shipped at points free from infection.

The Gulstonian Lectures for 1885, according to the "Lancet," will be delivered by Professor William Osler, of Philadelphia.

The Glycerin Pad Pessary is the name of a new contrivance described and figured in a recent issue of the "Lancet." "Pessaries," says our contemporary, "inflated either with air, water, or padded with muc-mucin or other substances, after a short period invariably become useless, as air escapes, water evaporates, and padding becomes hard. This invention is intended to obviate these defects; the padded end is filled with glycerin, which *always remains soft* [mirabile dictu], and yet offers sufficient resistance to render the instrument effective."

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 2, 1884, to November 8, 1884:*

SPENCER, W. C., Major and Surgeon. Ordered to Fort Trumbull, Conn., for duty as post surgeon, relieving Assistant Surgeon William J. Wilson, U. S. A., who will report at Department Headquarters and await further orders. S. O. 227, Department of the East, November 5, 1884.

CORBUSIER, W. H., Captain and Assistant Surgeon. Ordered to Fort Grant, Arizona Territory, for duty as post surgeon. S. O. 102, Department of Arizona, October 30, 1884.

HOPKINS, WILLIAM E., First Lieutenant and Assistant Surgeon. Ordered to Fort Lowell, Arizona Territory, for duty as post surgeon. S. O. 102, Department of Arizona, October 30, 1884.

EGAN, PETER R., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Lowell, Arizona Territory, and ordered to Fort Bowie, Arizona Territory, for duty as post surgeon. S. O. 102, Department of Arizona, October 30, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 8, 1884:*

CRAIG, THOMAS C., Passed Assistant Surgeon. To the Alliance for temporary duty, November 1, 1884.

SWAN, ROBERT, Passed Assistant Surgeon. Detached from the Naval Hospital, Norfolk, Va., and placed on sick leave, November 3, 1884.

WIEBER, F. W. F. Appointed Assistant Surgeon, November 3, 1884.

Society Meetings for the Coming Week:

MONDAY, November 17th: New York County Medical Association; Hartford, Conn., City Medical Society.

TUESDAY, November 18th: New York State Medical Association (New York—First Day); New York Academy of Medicine (Section in Theory and Practice of Medicine); New York Obstetrical Society (private); Medical Society of the County of Kings, N. Y.; Medical Association of Central New York; Ogdensburg, N. Y., Medical Association.

WEDNESDAY, November 19th: New York State Medical Association (Second Day); Northwestern Medical and Surgical Society (private); Roman Medical Society (private); New Jersey Academy of Medicine (Newark); Suffolk District Medical Society, Boston (Section in Obstetrics and Diseases of Women).

THURSDAY, November 20th: New York Academy of Medicine; New York State Medical Association (Third Day); New Bedford, Mass., Society for Medical Improvement (private).

SATURDAY, November 22d: New York Medical and Surgical Society (private).

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of November 6, 1884.

The President, FORDYCE BARKER, M. D., LL. D., in the chair.

The Pathology of Sensory Aphasia.—Dr. R. W. AMIDON read a paper with this title, based upon original observations in one case, and upon a review of the history of twenty-three other cases reported by different authors. In his own case, the patient, a female, aged sixty-four years, married, had been in perfect health up to nine years ago. At that time she began to suffer from flatulent dyspepsia, headache, and other neurasthenic phenomena. Six weeks before Dr. Amidon first saw her, which was in June, 1883, she was seized with severe pain on the left side of the head, which continued three days, when she became flighty and excitable, and vomiting took place. The right pupil was larger than the left, the tongue deviated slightly to the right, the right hand was not as much stronger than the left as it should have been, and was somewhat tremulous. There was no weakness of the right lower extremity, nor any marked disturbance of motility. The fundus oculi was normal, and acuity of vision was apparently perfect. With regard to speech, it was only in answering questions that she spoke incorrectly; she gave inappropriate answers to interrogatories. She could not count or say letters, but when she spoke of her own accord her remarks were connected and intelligible. She knew all her friends except her husband, and she called her son her father. She could not read, and could not be induced to write. She could hear well, and could sing correctly. She was subject to periodic attacks of a spasmodic nature, occurring at intervals of about a month, characterized by a cry, a drawing up of the right hand, and drawing of the mouth to the right, followed by general convulsions, sometimes with involuntary evacuations.

February 16, 1884, she was seized with a convulsion at 7 P. M., which continued until 11 A. M., the 16th, when she became comatose and died. During the last twenty-four hours of her life she had passed very little urine.

At the autopsy the kidneys were found to be the seat of advanced interstitial changes. The right cerebral hemisphere was normal. On the left side there was an irregular depression, with destruction of the cortex by softening, involving the inferior parietal lobule, the angular gyrus, and the second occipital and first temporal convolutions. There were atheromatous changes in the vessels supplying these parts, one of them being entirely occluded.

Dr. Amidon then presented eight diagrams, and read the histories of cases reported by several observers.

Of the twenty-four cases, in eight, with lesions affecting both the visual and the auditory regions of the left hemisphere, there were word-blindness and word-deafness; in two, in which the area of vision alone was affected, there was word-blindness; in fourteen, with the lesion in the auditory region, there was word-deafness.

Dr. Amidon drew the following conclusions: Word-blindness was an incapacity to understand speech, written or printed, vision and intelligence being preserved. It was generally dependent upon a destructive lesion of parts of the left side of the brain.

The Asiatic Cholera as it appeared at Suspension Bridge, Niagara County, N. Y., in July, 1854, and its Lessons; What we know of the Cholera.—Dr. FRANK H. HAMILTON read a paper with this title. [See page 533.]

Dr. L. M. YALE said that his own experience with cholera had been confined to the epidemic on Blackwell's Island referred to by the author of the paper. The report which he then made combined also the experience of his associates upon the Island. He would give a few points in the history of this epidemic. It broke out in the workhouse. It had been preceded by a period of great heat and of prevalence of diarrhoeal troubles throughout the Island. It became necessary, therefore, to put remedies in various parts of the buildings so that the patients could get them without the trouble always of searching for a physician. The water-supply for a time was cut off, owing to some defect, and the bread had been sour for a short time. There had before been some sporadic cases in Charity Hospital. By the third day after the outbreak in the workhouse Dr. Yale had thirty-three cases, twenty-three of which proved fatal, and about twenty per cent. of the entire number of inmates were carried off before the disease was finally checked. The epidemic occurred principally on the lowest ground of the Island. More women contracted the disease than men, and this might be accounted for by the fact that the men went out to work by day and their wards were larger. The women remained in the wards, and the evacuations stood in a tub, in a room where the inmates often remained for a considerable time in conversation with one another. Again, the patients, being unwilling to go to the Cholera Hospital, tried to conceal the fact when they were seized with diarrhoea. These faulty conditions having been corrected, the cholera was rapidly and permanently stamped out. There was one circumstance which was not easily explainable, namely, that in one pavilion as many as thirty cases of cholera developed, whereas in another pavilion, not thirty feet distant, not a single case occurred, although the conditions, so far as could be observed, were no better than in the other.

Dr. FRANCIS DELAFIELD supposed we would all admit that cholera belonged among the infectious diseases—a class of diseases which did not develop unless the body was infected by a specific poison. No matter how bad the influences under which human beings lived, with regard to soil, food, and hygiene in general, they might develop many other diseases, but they would not develop cholera unless there was added to these other favoring conditions the specific poison that belonged to the disease. Whether that specific poison had always to be imported into new

regions to develop the cholera, or whether it was capable of originating in new regions, might be a subject of dispute, but experience seemed to show that its home was India, and that other regions did not suffer until the poison was imported from India. If it was admitted that the disease was due to a specific poison, the question came up as to what that poison was. Here we had had all varieties of theories, none of which had proved particularly satisfactory. The latest theory, to which attention had been called this evening, was that, in accordance with the prevalent doctrine of the times, most of the infectious diseases were due to the presence and growth of certain minute organisms. Fashions of this kind in science and in medicine sometimes proved good and sometimes proved bad, and whether a given fashion would prove the one or the other could be known only after the lapse of some period of time. Dr. Hamilton had stated very fairly the evidence for and against this view of the causation of cholera. He had not stated, however, what Dr. Delafield considered particularly important to be borne in mind, that there were only a very few men whose testimony was of any value in speaking of the presence or absence of germs in disease, and the reason was the very great difficulty attending the experiments. Dr. Hamilton had called attention to the bearing which the condition of the soil and hygiene had upon the development of cholera, and this might be briefly expressed in this way, that whatever conditions of air, of temperature, of soil, of food, and of general hygiene, would predispose to the development of diarrhoea would also predispose to the spread of cholera. In other words, wherever there was a predisposition to diarrhoea, and also the specific poison of cholera, cholera would develop in its worst form and to the widest extent. If all these predisposing conditions were absent, the cholera-germ might find its way to the place and not produce cholera at all. This seemed to bring us to the means by which we could prevent its spread. In the present state of civilized society quarantine measures seemed to prove useless if commercial relations were to be continued with other countries. What we should do was to seek to remove every condition predisposing to the development of the disease.

Dr. A. L. LOOMIS said that his personal experience with cholera had been limited to a few cases which he saw in this city in 1866-'67, and he had therefore felt, when requested to discuss the paper, that he was largely in the position of one who was simply a student of the literature of the subject. It seemed to him that, at the present time, we might justly divide the infectious diseases into three classes, in accordance with the nature of their specific cause. The specific cause in the one class produced its disease on being transmitted to the healthy person directly from one already infected. There was no evidence that the exanthematous diseases were transmitted in any other way than by direct or indirect exposure to the contagion. The second class was that in which the disease was due to exposure to a poison developed outside of the human body, as in decomposing organic matter. The third class was that in which the poison developed within the living organism, and was capable of reproducing the disease only after having undergone certain changes subsequent to its discharge or removal from the infected person. To this class belonged typhoid fever and, he believed, also cholera. The home of cholera seemed to be Bengal, and epidemics in other parts of the world could always be traced as having originated there. He did not believe that cholera was ever of spontaneous origin. He then gave instances which went to show that in every epidemic of the disease its origin could be traced to spread of the contagion through soiled clothing, infected water, etc. The view that the poison was active only after it had undergone certain changes on being removed from the human organism was favored by the fact that those

making autopsies, those attending the patients, and microscopical observers of the fresh discharges, seldom contracted the disease. He was of opinion that the poison entered the body only through the mucous membrane, but not necessarily by way of the mouth and stomach. Sufficiently strict quarantine regulations would prevent the spread of cholera, but the difficulty of enforcing them had already been mentioned. The efficacy of the treatment spoken of by the author of the paper had been of great interest to him.

Dr. JOHN C. PETEES showed maps illustrating the spread of cholera from its home in India, and, speaking of preventing an epidemic in this country by quarantine, he said that so long as Denmark enforced her quarantine relations she had escaped cholera, whereas, as soon as those restrictions, on one occasion, had been removed, the poison was imported, and she, with neighboring countries, lost many inhabitants. Quarantine had also proved efficacious in Greece.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Meeting of September 11, 1884.

The President, Dr. JAMES TYSON, in the chair.

Cystic Papillary Adenoma of the Neck.—Dr. J. M. BAR-
TON presented a specimen which he had removed from a patient at his clinic at Jefferson Medical College on September 6th. The patient was a married woman, thirty-one years of age, the mother of three children. The tumor was of slow growth, having existed for five years, and having increased but little in the last two years. It gave rise to no pain and but little deformity. It was of about the size of a walnut and lay beneath the clavicular extremity of the left sterno-cleido-mastoid muscle in close proximity to both the subclavian and the carotid arteries, from which it received a decided pulsation; on strongly pressing the tumor upward and outward the pulsation ceased. The tumor was closely adherent to a number of large veins of new formation, which greatly increased the difficulties of its removal. On section, it presented a number of alveoli, of variable diameter, communicating with each other and lined with a thick membrane, similar in appearance to the inner coats of the arteries. This membrane seemed to have undergone calcareous degeneration in some portions. When the tumor was fresh these cysts, on incision, were filled with a dark-red fluid like disintegrated blood.

On the 9th of October the Committee on Morbid Growths reported in regard to this specimen that a section made from it showed a stroma of fibrous tissue, in which cavities were seen, varying in size, and lined with an epithelium having a cuboidal shape. From the margins of many of these cavities papillary ingrowths were noted, covered with cylindrical-shaped epithelium; others were filled with the remains of cells or a structureless, colloid substance. The tumor might, therefore, be considered a cystic papillary adenoma in which a colloid degeneration had occurred, or, from its location, it was not improbable that it might be either an outgrowth from the thyroid gland or a supernumerary gland.

NEW YORK SURGICAL SOCIETY.

Meeting of October 28, 1884.

The President, Dr. ROBERT F. WEIR, in the chair.

Deformity of the Hands from Cicatricial Contractions, following Extensive Burns.—Dr. A. C. POST presented a patient under treatment for complicated deformities of the hands from burns which were inflicted nearly two years ago. The patient was a young woman, who attempted by gaslight to wash with

benzin long kid gloves which were on her hands and forearms. The benzin took fire, and the forearms and hands were very severely burned. She came under Dr. Post's care within a few weeks after the injury, but it was a long time before the burns were sufficiently healed to enable him to take any active measures to correct the deformities which they had occasioned. Within the last year a series of operations had been performed chiefly to overcome the forced flexion of the fingers at the articulations between the first and second and second and third phalanges. And these operations had been attended by a gratifying measure of success. The last operation was performed nearly seven weeks ago. It was designed to overcome an exaggerated extension or backward flexion at the metacarpo-phalangeal articulations. It consisted in numerous oblique incisions across the back of the hands and fingers, extending through the whole thickness of the cicatricial tissue, and dividing it into small rhomboidal segments. The fingers were then forced into a bent position nearly at right angles, and held in that position by narrow splints of malleable iron, one for each finger, applied to the palmar surface of the finger, hand, and forearm, and held in place by strips of adhesive plaster and roller bandages. Before the splints were applied the wounds were washed with a solution of mercuric bichloride, and dusted with subnitrate of bismuth. The wounds were healed within twelve days from the time of the operation. The dressings had been repeated three times a week, passive motion being made freely at each dressing. For the last three weeks the splints had been left off for half a day before each dressing, and active and passive movements had been freely resorted to. The backward flexion of the phalanges had been entirely overcome, and the patient was regaining the use of the fingers. Dr. Post made the remark that in the division of cicatricial bands the wounds healed more rapidly, and with less irritation, when a large number of incisions were made than when the incisions were less numerous and with wider intervals between them.

Hyperplastic Follicular Goitre.—Dr. A. G. GERSTER presented a patient, a female, twenty-four years of age, a native of Bohemia, where goitre could not be said to be endemic, from whom twenty days ago he removed the right half of the thyroid gland. The patient said that she had had the goitre since her childhood, and also that about ten years ago she had some exophthalmus, and suffered somewhat from palpitation of the heart. About one year ago the goitre began to grow rapidly and was still growing, and extended upward and backward along the course of the sterno-cleido-mastoid muscle, its length in this direction measuring three inches and a half. She also began to suffer from dyspnoea, especially when going up stairs or walking rapidly, and desired the removal of the tumor. Puncture being performed, no liquid was found. Examination of the growth after its removal revealed that fluctuation was due to gelatinous deposits in the tumor.

It might be asked why he had not resorted to other methods of treatment before performing extirpation. The chief reason was that he felt at the lower portion of the tumor two distinct nodules, probably calcareous in character, and subsequent examination showed that the assumption was correct. The method of removal was by a flap incision, commencing at the middle of the anterior margin of the sterno-mastoid, carrying it around the circumference of the tumor and back to the lowest point of the border of the sterno-cleido-mastoid muscle. The capsule having been exposed, the enlarged body was dissected out in the usual manner by dividing such strands of tissue as had been grasped between the blades of forceps. From seventy to seventy-five ligatures were required in dissecting out the entire tumor, and not more than an ounce of blood was lost during the operation. The tumor was very closely adherent to

the anterior portion of the trachea and cricoid cartilage, and at that point dissection was most difficult. The wound was united by a number of deep sutures. The muscles which were cut were the sterno-hyoid and a large portion of the sterno-cleido-mastoid on the right side, which were united with catgut sutures, and finally the flap was attached with two continuous sutures, and an ample dressing, consisting of some iodoform gauze and a bag of sublimate sawdust, was placed over the wound. Union by first intention took place except at one point, where an absorbable drainage-tube had been introduced, and where a few granulations remained. The tumor exhibited represented the right lobe of the thyroid gland. The left lobe was normal, and was allowed to remain.

Dr. Gerster thought the flap operation preferable in these cases to the longitudinal incision, as it gave more room.

The Secretary, Dr. L. M. YALE, then read the thesis of a candidate for membership.

Spontaneous Fracture of both Femora.—Dr. L. A. STIMSON presented specimens from the case of a man, fifty-one years of age, who was admitted to Bellevue Hospital October 16, 1884, and died October 23d. He was a carpenter, and had always been robust and healthy until last winter, when he began to feel weak and to suffer from aching pains in both thighs. The pain continuing, he ceased to work, but did not take to his bed. His strength diminished, and he lost flesh. The day before admission, while walking across the room, he caught his toe in the oil-cloth, fell, and was unable to rise. On admission, each femur was found to be broken at about the junction of the upper and middle thirds. He healed rapidly, without fever or complaint of pain, became dull and semi-unconscious, and died on the eighth day. Examination of the urine showed a specific gravity of 1.004, but no albumin or casts. The autopsy revealed only a large stone in the pelvis of each kidney. These were shown, one weighing five ounces and six grains, the other one ounce and four hundred and thirty-two grains.

The portions of the femur presented were those adjoining the fractures. All four pieces showed an advanced stage of osteoporosis. The compact tissue and the wall of the shaft had almost entirely given place to frail, spongy tissue. Scales of bone fell off at the touch, and one of the fragments had almost crumbled to pieces by the slight handling it had received since its removal. The diameter of each bone was as great as usual, but the medullary canal was very large. Each canal was occupied by a dark blood-clot nearly two inches long. Examination of the other bones was not allowed. A fragment of bone that weighed twenty-nine centigrammes, after having been boiled and dried, was decalcified with nitric acid, and then weighed eleven centigrammes, which indicated that the percentage of inorganic matter in the specimen did not differ materially from the normal. The kidney showed dilated pelvis and calices, with marked atrophy of the cortical substance, and it was remarkable that with stones of that size there was no evidence of kidney disease either irritative or obstructive in character.

Foreign Body in the Urethra and Bladder.—Dr. STIMSON also presented an ordinary lead-pencil removed from the penis and bladder of an unmarried man, forty-six years of age. The pencil was seven and one sixteenth inches long, had been in place forty hours, and was removed through a perineal incision. The patient said he introduced it because he found himself unable to urinate; but there was nothing in his history or in the condition of the urethra to confirm the excuse.

Dr. Post had had occasion many years ago to remove, through a perineal incision, a short piece of lead-pencil from the neck of the bladder. The piece had been sharpened at one end, and the patient had taken the precaution to make it smooth by covering it with a little ball of sealing-wax.

Tumors of the Bladder; Cystotomy.—Dr. J. L. LITTLE presented a number of tumors which he had removed from the bladder of a patient in St. Luke's Hospital, who gave the following history, which was kindly furnished by Dr. Ludlow, of the house staff: "James McA., aged forty-nine, married, a card-driver by occupation, and a native of Ireland. His family history is good. About eight years ago he had a sudden hæmorrhage from the bladder while urinating. For two days previous he had frequent micturition and pain at the symphysis pubis. From this time up to one year ago the hæmorrhages recurred at intervals of three or four months, and lasted about as many days. During all this time micturition was not very frequent, and he continued at work. About one year ago the quantity of urine voided steadily diminished for about one week, and then stopped altogether, and it was necessary to resort to catheterization. Since this time he has constantly used the catheter, as he has been unable at any time to pass more than a small quantity of urine, and that with great pain. The desire to urinate has become more frequent. The patient was sent to Dr. Little's clinic at the post-graduate school, by Dr. W. B. Wallace, about two months ago.

"On examination, no calculus was found, and it was discovered that the introduction of a sound or a soft catheter was always followed by a fresh hæmorrhage into the bladder. He was able to hold his urine without pain for six or eight hours at a time. The symptoms indicating a growth in the bladder, he was sent to St. Luke's Hospital for an exploratory operation. A consultation was held and the operation advised. An examination of the urine showed pus, blood, mucus, and triple phosphates. No casts or shreds of tumor were found.

"On October 27th Dr. Little performed median cystotomy. On introducing the finger, a number of soft tumors could be detected. These were situated at the trigone of the bladder, between, and extending beyond, the orifices of the ureters. A number could also be felt attached to the upper surface of the bladder. The situation of these growths being distinctly made out by the finger, Thompson's tumor forceps was introduced, and the tumors were seized and twisted or bitten off from their attachments. It was found necessary to enlarge the opening in the bladder by a slight incision downward toward the prostate in order to introduce the forceps with facility. Twenty distinct masses, most of them seeming to be separate tumors, were removed. These varied from the size of a hazel-nut to that of a hickory-nut. They all seemed to be villous in character. A large number of small pieces, evidently torn off from the larger tumors, were also removed. The surface of the bladder, after the removal of these growths, was left considerably roughened. Two orifices, large enough to allow of the introduction of the tip of the finger, could be felt in the situation of the openings of the ureters. These seemed to be the dilated orifices of the ureters. The hæmorrhage during the operation was considerable, but not enough to be alarming at any time. After the operation was completed, the bladder was thoroughly washed out with hot boro-salicylic-acid solution. This seemed to greatly lessen the hæmorrhage. The wound was left open, no tube or catheter being used. During the evening following the operation the hæmorrhage was very free at times. Dr. Hance, the house surgeon, tried injecting a solution of tannic acid without effect; finally he succeeded in controlling the hæmorrhage by packing the rectum with ice, and applying ice-bags over the pubes.

"October 28th.—Patient's condition is good. Temperature 99° F., urine stained with blood."

Since the last notes in the history furnished by Dr. Ludlow, and read to the society, the patient had been steadily improv-

ing, passing nearly all his urine from the penis without pain, free from hemorrhage, and without recourse to a catheter. The microscopic examination of the tumor would be reported at the next meeting.

Rupture of the Bladder (Intra-peritoneal) with Fractured Pelvis; Laparotomy and Suture of the Bladder; Death.—Dr. W. T. BULL presented a specimen with this history:

A laborer, forty-six years of age, was brought to the Chambers Street Hospital October 27, 1884, at 12.27 P. M., having fallen from the first floor to the cellar through a heater-shaft, a distance of sixteen feet. He was unconscious on admission, respirations 31 and shallow, pulse 96, temperature 95°, surface cold. He presented evidences of the following injuries: Lacerated wounds of the right temple, fracture of the left radius (Colles's), and fracture of the right side of the pelvis, the exact location of which was not made out. Three hours later, while he was still unconscious, a catheter was passed into the bladder without difficulty, and one ounce and a half of bloody urine withdrawn. Temperature 97.5°, pulse 78, respiration 40. A No. 30 (F.) steel sound was passed readily. An hour later half an ounce of bloody urine was withdrawn by the catheter, and about the same amount for three successive hours. Stimulants and the hot-air bath were used, and the man gradually regained consciousness. He had been very restless, and complained of pain in the lower part of the abdomen, but evinced no desire to urinate. P. 120, weak; R. 44; T. 97.5°. There was dullness in both iliac regions, the hypogastrium, and half-way to the umbilicus. There was no pronounced swelling. On introducing a black rubber catheter as far as the bladder, one ounce of bloody urine was withdrawn, but two ounces with clots were expelled when the instrument was pushed to a depth of eleven inches from the eye of the catheter. With a silver catheter the point gave to the finger the impression of engaging in a mesh of soft tissue after it had been passed quite beyond the ostium urethrae internum. At midnight, twelve hours from the time of injury, P. 150, R. 44, T. 96°. An hour later the condition had changed but little—T. 97°, P. 140, R. 44. Dr. Bull saw the patient at this hour with Dr. F. W. Murray, and, feeling certain, from a consideration of the symptoms above enumerated, that a rupture of the bladder had occurred, either into the peritoneal cavity or into the subperitoneal tissue anterior to the bladder, decided to make an exploratory incision into the abdominal cavity. Ether was administered, Dr. Murray and the house surgeon, Dr. Mack, assisting. Before the incision was made, it was ascertained that the pelvis was fractured only through the body and descending ramus. After the subperitoneal connective tissue was opened, much blood, but no urine, was found to be extravasated in its meshes. On cutting through the peritoneum to the extent of three inches, several ounces of thin bloody fluid, apparently urine, escaped, and the small intestine floated into the wound and obscured both vision and touch. The presence of the intestines rendered further exploration so uncertain that he extended the abdominal incision to five inches, drew out all the coils of intestine that were accessible, and held them on the left side protected by towels wet with warm water. The bladder was now drawn upward and forward over the symphysis, and held with a hook. A rent was now plainly seen in its posterior wall, commencing just below the point of its peritoneal covering and extending an inch and three quarters backward. Its edges were slightly everted, displacing the mucous membrane, and a catheter, introduced *per urethram*, emerged through the rent. The wound in the bladder was then closed by seven carbolized-silk sutures introduced from below upward, and passed, like a Lambert's intestinal suture, through the peritoneal coat only. It was ascertained that the sutures were placed at intervals of one eighth to one quarter of an inch. The bloody fluid and a few clots were

then sponged out of the abdominal cavity, the intestines were replaced, and the incision in the parietes was closed with four silver-wire, six silk, and thirteen catgut sutures. A dressing of iodoform and absorbent cotton was applied, a small rubber drain being left at the lower angle of the wound. A soft rubber catheter was tied in the bladder. He chose this method of drainage of the organ in preference to a median cystotomy, because he thought it would be more efficient, while the care of a perineal wound would be likely to interfere with the quiet necessary for the proper management of the fractured pelvis. Again, the patient's condition did not permit continuing the operation longer than was necessary, and it seemed to him that the cystotomy could be done subsequently if the catheter did not drain the bladder satisfactorily. The operation lasted one hour, and during its performance tincture of digitalis and whisky were several times injected subcutaneously. At its close the pulse was 130, but of better volume and stronger than before; respirations 40, and shallow. One could truthfully say that, notwithstanding the operative attack and the etherization, which was conducted with great care, the man's condition was no worse than before it was begun. In spite of all efforts to improve his condition, the man died comatose seven hours after the operation, and at his death two ounces of clear urine passed through the catheter.

Only an incomplete autopsy was possible. Dr. Murray, who kindly examined the body, had reported to Dr. Bull that on opening the abdomen he found much extravasated blood in the subperitoneal tissue of both iliac and the right lumbar regions, the pelvis fractured through the body and descending ramus of the right side, and the fragments of the horizontal portion separated by an interval of one inch. The peritoneal cavity contained no urine; the intestines were healthy, but Douglas's *cul-de-sac* contained about one ounce of fluid blood. The urethra, rectum, and bladder were removed *en masse*, and presented no lesions except some submucous ecchymoses in the bladder, and the rent, closed by suture, in the posterior wall of the bladder. Before opening the organ, however, it was filled with water through a funnel introduced into the urethra. A little water escaped between the two lowest sutures. It was found that, while the other sutures had been introduced at pretty regular intervals of from one eighth to one quarter of an inch, these two sutures covered an extent of tissue equal to half an inch. The wound in the mucous membrane had about the same extent as those of the peritoneal coat, an inch and three quarters, and its edges were gaping inwardly. The bladder was completely empty and contracted. The kidneys were healthy. Other parts could not be examined.

Dr. Bull said that he had felt justified in giving the patient the chance of the operation in spite of his other injuries, feeling sure of the diagnosis, and knowing that his greatest danger was from the extravasated urine and blood being allowed to remain in the peritoneal cavity. He had been surprised at the fact that, after opening the peritoneal cavity, the intestines, though not distended, were so much in the way that he could gain no idea of the state of the bladder save that it was empty, and he believed that by putting them aside he had done no harm, and gained much in time and the facility of exploring the bladder-wound. It was not easy to introduce the deepest sutures. He had made every effort to close the wound carefully, but had failed, as the injection of the bladder on autopsy showed, to do so perfectly at its deepest part. At the same time, he thought that, as the adhesion of the peritoneal membrane took place so rapidly, occurring, as examinations after ovariectomy had shown, in from six to twelve hours, the wound would not have "leaked" had the patient lived. This seemed all the more likely as the drainage through the catheter was

perfect, two ounces having flowed away in the seven hours before death, and the bladder being found quite empty and contracted.

BROOKLYN PATHOLOGICAL SOCIETY.

(Concluded from page 526.)

Aneurysm of the Right Subclavian Artery involving the Innominate; Death.—Dr. PAUL H. KRETZSCHMAR related the case of a German farmer who came under his observation in September, 1881. He was at that time sixty-one years of age, and he had enjoyed perfect health until about nine months previous, when he commenced to experience shortness of breath while working on his farm. A troublesome cough and hoarseness induced him to obtain medical advice from a practitioner in his neighborhood, and, following the advice given, he sold his farm and came to Brooklyn to live a perfectly quiet life. When Dr. Kretzschmar first saw him he complained of increased dyspnea, of considerable cough with free expectoration of tough, whitish mucus, and of occasional hoarseness. He said that he had lost his former strength, and that he was unable to walk fast or go upstairs; he presented the picture of a prematurely old man.

A physical exploration of the chest revealed aortic and mitral murmurs with both sounds of the heart, and a diagnosis of valvular disease was made at that time. Notwithstanding proper medical and hygienic treatment, the symptoms increased in severity, the hoarseness lost its intermittent character and became permanent, and the patient commenced to complain of very severe pain on the right side of the neck, extending both up toward the right side of the face and down to the axilla. After two months the right radial pulse was weaker than the left, and the two were not synchronous. The area of cardiac dullness was not perceptibly enlarged, but there was a marked change in the character of the sounds at the aortic valves, and the murmurs, which at first could only be heard at the seat of the valves, could then be traced along the upper border of the clavicle. These symptoms, together with a well-defined area of dullness in the supraclavicular space, led him to change the diagnosis to aneurysm.

The very favorable results which he had obtained from the use of large doses of iodide of potassium in cases of aneurysm induced him to put the patient on the use of half-drachm doses of the drug every two hours, and to order perfect and absolute rest. This treatment was continued for about three months, and the patient showed marked signs of improvement. The severe pain, which previously had prevented sleep, disappeared entirely, and the troublesome hoarseness improved. In fact, he did so well that he lost sight of him for six or seven months. When he saw him again, during the latter part of 1882, the former unpleasant symptoms had recurred with increased severity, and a pulsating tumor could be felt at the upper border of the right clavicle. The patient declared positively that his stomach could not stand any more of the medicine which he had taken previously, and that he would not take it if it was prescribed. He was then put for ten days on the use of acetate of lead, in doses of two grains four times a day, and afterward he was given drachm-doses of Squibb's fluid extract of ergot four times daily, without the slightest sign of beneficial action. Tonics, cold compresses over the tumor, and anodynes were used according to symptomatic indications. One night in May, 1883, he was called suddenly to see the patient, and found him bolstered up in bed gasping for breath, the perspiration rolling down his cyanosed face, and his pulse feeble and irregular. Iodide of potassium, disguised, was ordered again, in forty-grain doses, every two hours, and the following day the man was much better. So long as the administration of the iodide was continued

the patient improved, but, when he refused to take any more of it, the disease became progressive and the size of the tumor increased. During the autumn of 1883 it became apparent that a large portion of the first rib on the right side had been absorbed by pressure, and after that time the tumor grew very rapidly. Shortly before death it had acquired its largest size, resembling the protruding occiput of an infant during delivery. The patient died May 17, 1884. The autopsy was made Dr. Hunt the following day, and the aneurysm, together with the large vessels and the heart, was removed. The President would kindly demonstrate the specimen.

The interesting points in the clinical history of this case were: 1. The fact that the diagnosis was made more than three years before the fatal termination took place. 2. The decided and beneficial influence which large doses of iodide of potassium had on the disease, especially the relief from the most severe pain, which was obtained repeatedly and almost instantaneously after the use of the drug. 3. The large size which the tumor acquired so rapidly after the first rib had been absorbed.

Pernicious Anæmia.—The President presented the stomach from a woman who had died in his service at St. Mary's Hospital, and in whose case there had been some question as to the diagnosis. She was a single woman, thirty-eight years old, a native of Ireland. She had been sick for about two years. The first symptoms noted were those of indigestion and anorexia. Vomiting soon appeared, occurring directly after eating, and the matter ejected consisted of undigested food. After these symptoms had continued about a year, she noticed a swelling of the feet and some puffiness of the face. The abdomen had never been swollen. About four months prior to her admission the vomit began to look dark-colored, and, still later, yellowish and frothy. She described it as having the appearance of frog's spawn. She was not aware of having vomited blood at any time. For some months there had been cough, with a thick, tenacious sputum. She was also troubled with constipation and headache.

On admission, her appearance was that of extreme anæmia, with a pretty-well-marked icterode hue. Though somewhat thin, she was not greatly emaciated; the tissues were soft, succulent, and flabby. The radial pulse and the apex-beat were feeble, and a moderately loud blowing sound was heard at the left of the sternum, in the second and third intercostal spaces. The area of cardiac dullness was somewhat extended. There were no physical signs of pulmonary disease other than those indicative of anæmia—viz., increased resonance and prolongation of the expiratory murmur. The hepatic dullness extended two or three inches below the costal cartilages, and the liver remained in contact with the anterior wall of the abdomen. The epigastric region was tender upon pressure, and she complained of a burning and stinging sensation extending upward, from this to the sternal region. The urine contained a slight quantity of albumin, but no casts were discovered. The patient was extremely weak, and the constant vomiting had reduced her to such a state of prostration that an ophthalmoscopic examination was not attempted. The diagnosis lay between chronic nephritis, carcinoma of the stomach and liver, and pernicious anæmia. Owing to the jaundice, epigastric pain and tenderness, extension of hepatic dullness (though without a nodular surface of the liver), and the fact that, on the second day after admission, the vomited matter contained blood, together with the total inability to retain anything upon the stomach, the probabilities were thought to be in favor of carcinoma. The albuminuria was attributed to the extreme anæmia and adynamia. The treatment consisted in the administration of the ordinary remedies for vomiting and anodynes. The bowels were moved by enemata. In spite of every effort, the emesis continued, and,

on the twelfth day after admission, she vomited a basinful of blood, after which she rapidly sank, and died within twenty-four hours. The autopsy was made by Dr. A. H. P. Leuf, pathologist to the hospital, and the following is his report:

Autopsy.—Body well nourished; skin yellow; rigor mortis very slight. The lungs were both extremely pale and emphysematous in the upper and anterior parts. The left apex only was slightly adherent. There were numerous slight pinkish subpleural ecchymoses over both lungs. The transverse, or left innominate, vein was cut in removing the heart. A stream of blood about 3 mm. in diameter spurted out for fully one minute, describing an arc of a circle having a radius of about 5 cm. The blood was almost perfectly clear, looking as if it had been diluted with water to such an extent that it formed but 25 per cent. of the bulk. No clotted blood was found anywhere. There was dilatation of the tricuspid and bicuspid orifices, especially of the latter, which admitted four fingers to the middle joint. The stomach and gut were normal. The liver was soft and slightly enlarged, projected down to the umbilicus, and was very yellow. It was bound to the diaphragm by old adhesions. The common bile-duct was distended and full of bile. The pancreas was normal. The spleen was normal in size, but very dark and firm. Both kidneys had distributed irregularly throughout their substance numerous small ecchymoses. Each was anæmic, but the right one less so than its fellow. The uterus was atrophied and imbedded in a fibroid fully 3 cm. in diameter. Another fibroid projected from the right upper angle of the main growth; and yet another, having a sessile attachment, was found projecting from the left lower aspect of the large growth. The last one mentioned was about 2 cm. in diameter and the other about 1.5 cm. Both ovaries were long, narrow, flat, and markedly senile.

The PRESIDENT stated that, in bringing the case before the society, he was conscious of the defects in its history, but presented it as one of great clinical interest, and for the purpose of obtaining the views of the members as to the propriety of classifying it under the head of pernicious anæmia.

Dr. KRETZSCHMAR, after having listened to Dr. Westbrook, still held the view he had formerly expressed to that gentleman, and that was that his case was not one of pernicious anæmia. As he took it, pernicious anæmia only occurred when no pathological lesion could be discovered at the autopsy. It was essentially a disease of the red-blood corpuscles. It was not an anæmia pure and simple. If the leucocytes of the blood should be increased it could not be called pernicious anæmia, but it was essential to the production of this disease that the normal quantity of red globules should be actually and considerably diminished. The marrow of the long bones had not been examined in this case. According to Biermer, a case could not be called one of pernicious anæmia that showed any anatomical lesion of the viscera. Because the examination in this case had been incomplete, and on account of the lesions found post mortem, he declined to consider it a case of pernicious anæmia.

Dr. SAMUEL G. ARMOR said it could be stated as a general principle that those were all cases of pernicious anæmia in which the anæmia was intense without any discoverable local cause, and without any revelations of a pathological nature after death. He quite agreed with Dr. Kretzschmar. All those anæmias associated with pathological changes were secondary. This was a general principle. All others formed the group of idiopathic or essential anæmias. He believed that the cause of the anæmia in Dr. Westbrook's case was really in the stomach. He also thought that a large proportion of the cases reported to be cases of pernicious anæmia were really due to gastric changes. He would call attention to Dr. Flint's writings upon the subject, who maintained that many cases, like the one before us,

together with cases of Addison's disease, had their cause in the stomach. He still believed the anæmia in Dr. Westbrook's case to have been the result of a diseased stomach.

The PRESIDENT thought the question was one of nomenclature. Dr. Kretzschmar was right in saying that, according to Biermer, with whom the term "progressive pernicious anæmia" originated, this was not a case of that disease; nevertheless, there was a difference of opinion among clinicians as to what the term should mean. Quincke, for instance, included under the head "pernicious anæmia" many instances of profound anæmia in connection with obvious disease of the viscera. Dr. Flint, as Dr. Armor had observed, had long ago prophesied that the lesion in these cases would be found in the digestive apparatus, probably in some degeneration or other morbid process in the stomach. There had recently appeared, in Virchow's "Archiv," an account of some researches by Sasaki, in which he had found changes in the nervous plexuses of Auerbach and Meissner; fibroid and hyaline changes in connection with the microscopic ganglia of these local nervous mechanisms, which were connected—the one with the muscular, the other with the mucous layer of the intestinal walls. In this case, the only discoverable lesion, beyond a fatty degeneration of the liver, was in the mucous membrane of the stomach. It was evident that the condition of the liver could not, by itself, account for the history of the case. To what extent the changes in the stomach could be held responsible could only be determined on the report of the Microscopical Committee.

Dr. ARMOR asked if there had not been some new light thrown upon Addison's disease. He had the impression that some one had pretty well determined that it was always associated with changes in the abdominal sympathetic ganglia.

Dr. FERGUSON replied that the President's German authority included Addison's disease among the pernicious anæmias, and that he had examined the sympathetic plexuses of the gut, kidneys, and supra-renal capsules, but he thought with not very positive results.

An Acardiac-acephalous Monster.—Dr. W. J. BRANDT reported that, on the 21st of August, he was called to see Mrs. G., and found that she had had a miscarriage at about the third or fourth month. It was a case of twin conception, and one fetus was wanting in arms and head. The placenta was shut up in the uterus so firmly, and the vagina was so small, that he was unable to remove the former; so he gave a full dose of ergot, and the next morning the placenta was found in the vagina.

After reading a passage from Ziegler's "Pathology," descriptive of such monsters, and of the mode of their formation, Dr. Brandt said that dissection of this specimen showed the framework of the thorax to be fairly developed, the sternum and ribs being present, but there were no contents. The abdomen contained only a very primitive intestine, but there were well-developed kidneys. No other viscera were present. On opening the vertebral canal, the spinal cord was well shown, extending to the lower end of the spine, and not stopping in the lumbar region. The subcutaneous tissue of the upper end of the specimen was infiltrated with a mucus-like substance. The feet were both deformed, one being in the condition of talipes calcaneus and the other in that of talipes equino-varus. On one foot there were two toes only, and on the other three. Both fetuses were males.

AMERICAN PUBLIC HEALTH ASSOCIATION.

(Concluded from page 531.)

Thursday's Proceedings.

The Sanitary Care of Cattle in Transportation.—At the morning session Dr. W. B. CONNERY, of Missouri, read a paper

on this subject, with special reference to the splenic fever of Texas cattle. Under the best of circumstances, the journey made by the vast herds of cattle from the ranches of the West to the great midland and eastern cities was attended with almost insuperable hardships, owing to the great distance traveled, and the want of food, drink, and space. It was not uncommon for cattle to be shipped from St. Louis to New York with only one break in the journey. The cars should not be overloaded, and they should be thoroughly cleansed and disinfected after each shipment. There should be an abundance of fresh air provided, and the animals should have plenty of good water and have access to salt-pans. They should be inspected daily, and those that were in bad condition should be removed from contact with the others.

A Proposed Health Exposition at New Orleans, in connection with the World's Exposition to be held in that city, was the subject of a preamble and resolutions introduced by Dr. S. S. HERRICK, of New Orleans, in behalf of the Hon. John Eaton, U. S. Commissioner of Education. They were referred to the Committee on Resolutions.

Dr. COVERTON, of Toronto, invited the association to hold its next meeting in that city.

Reports of Committees were read as follows: Of the Committee on Cattle Diseases, by Dr. J. M. PARTRIDGE, of Indiana; and of the Committee on Epidemics, by Dr. A. N. BELL, of New York. Dr. JOSEPH HOLT, of Louisiana, read a separate report on "Quarantine Sanitation," in which he opposed the system by detention, and described the plan pursued in New Orleans.

The Sanitation of the Mississippi Valley was the title of a paper by Dr. G. B. THORNTON, of Tennessee. The Mississippi River bottom, he said, lying between the 37th and 29th parallels, or between Cairo and New Orleans, a territory of 32,000 square miles, was one of the richest sections in the world. It contained alluvial bottoms, was subject to annual overflows, and many places, once under cultivation, must necessarily be abandoned and thus revert to their wild state. This country was the true habitat of malarial diseases of all kinds. There was a marked difference in susceptibility to these diseases between whites and negroes, the former being far more susceptible than the latter and not standing exposure so well during summer and autumn. This section had been visited by yellow fever and cholera on several occasions. The sanitation of the valley depended upon the following measures: 1. The reduction of the causes of malarious atmosphere to the minimum. 2. Improvement in the present method of living. 3. The prevention of the introduction of the infectious diseases above mentioned. The swamp lands were enormous, but the intensity of the disease seemed to vary with different years, owing to a difference of atmospheric conditions. Overflows did not inevitably cause an increase of malarial or other disease, and they did not usually either cause or promote epidemics, therefore they were not commonly dreaded. There was no adequate index to the condition of the bottom countries so far as health was concerned. Malarial diseases prevailed most largely in the latter part of summer and autumn, when the ground was covered with dew and the air was moist. The conditions necessary for the production of malaria were a heat of from 67° to 70° F., permanent moisture, and vegetable decomposition or emanations. The first essential step in prophylaxis was to reduce to the minimum the two elements which were to some degree controllable—moisture and vegetable decomposition, or the miasmatic emanations of the soil. The seasons being immutable, the heat could not be modified. Civil and sanitary engineering could so dispose of the water distributed over this country by the excessive spring floods and annual rainfall as in a measure to control this element. This

would require an effective system of levees, canals, and reservoirs. The third factor, decayed vegetable matter and the deleterious elements of a fresh soil, was in course of removal by the constant clearing and cultivation of lands for agricultural purposes. The work of building levees, draining bayous, lakes, and stagnant pools, and removing the deleterious ferments of the soil by cultivation was a slow process toward the sanitation of this vast delta. In the mean time it would be well to consider the best methods for the preservation of health in the face of these opposing elements. The resistance to malaria could be increased by improved methods of living, especially among those not acclimated; good food, wholesome drinking-water, suitable clothing, keeping out of the night air, strict abstinence from whiskey, and comfortable houses would greatly facilitate the struggle with the disease. Individual hygiene was a necessity, but the class who observed it was very limited, and it might be said that there were fewer people in this section of the valley who enjoyed the comforts of home life than in any other section of the Union. Those suffering most were Northern, often European, laborers working under contract. They had to live in miserable huts, with poor food and clothing, were usually sallow, had enlarged livers and spleens, and suffered from what they called swamp fever. Now that Congress had spent five millions to deepen the mouth of the Mississippi, and had appropriated money for the construction of levees to prevent overflows, the question had become one of more than local interest. Protection from overflows in the Northern States had become a matter of vital interest to the people of the North and the South. This section was the agricultural center of the country, and contributed more to its wealth than any other. It seemed to be agreed that levees were the best protection against overflows. Reservoirs at the head of the tributaries of the Ohio, the straightening of channels by cut-offs, the closing of bayous and crevasses, and the formation of levees, were the most practicable means of prevention.

The Present and Future of Water Analysis was the title of a paper by Dr. CHARLES SMART, of the army.

The Pollution of the Upper Ohio, and the Water Supply of its Cities and Towns.—Dr. JAMES E. REEVES, of West Virginia, read a paper with this title, in which he said that the health and probable length of life of a people might be measured by the quality and quantity of its water supply. In view of the refuse of all kinds that was thrown into the upper Ohio, it should not be a matter of surprise that the death rate from typhoid fever and diarrhoeal diseases was high in the region in which its waters were used. But it was not ordinary filth, as such, that was the source of danger, but certain specific germs that were apt to accompany it.

The Relation of the Depth of Water in Wells to the Causation of Typhoid Fever.—Dr. HENRY B. BAKER, of Michigan, read a paper in which he showed a relation between a low level of the well-water and a high mortality from typhoid fever in Michigan. This was to be explained by the greater ease with which refuse matter percolating through the soil ran into the wells under such circumstances. Typhoid fever could be prevented by avoiding contaminated water, but the prevention of the contamination of the well-water was by no means an easy matter.

The True Value of Chemical Analysis in determining the Hygienic Purity of Potable Water was the subject of an interesting paper by Dr. T. M. STEVENS, of Indiana.

Prize Essays.—Mr. HENRY LAMB, of Rochester, N. Y., offered to give the association \$2,000 to be contended for next year by those contributing papers, the subjects being divided as follows:

First, "Healthy Homes and Food for the Working Classes,"

\$500. *Second*, "On the Sanitary Conditions and Necessities of School-houses and School Life," \$500. *Third*, "On Disinfectants and Individual Prophylaxis against Infectious Diseases," \$500. *Fourth*, "An Appliance and Means for Saving Life, and for Protection against Injurious Influences of some Work and Occupations on Health," \$500. Essays to be ready April 5th, and to become the property of the association. Mr. Lamb also agreed to give \$50 to defray the expenses of a committee on disinfectants. A committee, to consist of five members, one to be named by the National Board of Health, three by the Executive Committee of the Public Health Association, and one by the President of the Conference of State Boards of Health, was asked to be appointed for the examination of essays and awarding of prizes.

The donation was accepted by a rising vote and the matter referred to the Committee on Resolutions.

Other papers were read as follows: "The Manufacture of Soda-Water from Polluted Well-Water," by Dr. FRANK R. FREY, of St. Louis; "The Relation between Underground Sewerage and Filth Diseases," by Dr. S. S. HERRICK, of Louisiana; and "The Chemical Disposition of Sewage," by Dr. W. J. HAREIS, of St. Louis.

The Germ Theory of Disease was the title of a paper by Dr. G. M. STERNBERG, of the army, who gave a summary of the work of Koch, Pasteur, and several other investigators, as well as of some of his own researches. He had not been able to find the microbe of yellow fever, and he doubted if it was to be found in the blood; perhaps it would be found in the intestinal discharges. The paper was exceedingly well illustrated with views projected on a screen, displaying a great variety of the lower organisms.

The Bearing of the Discovery of the Tubercle Bacillus on the Public Health.—Dr. L. BREMER, of St. Louis, read a paper with this title, in which he said that there were some people who denied that Koch's discovery marked a progress in practical medicine, because it had added nothing to the treatment of consumption. This must be admitted. Phthisis was today as it had been before the demonstration of the tubercle bacillus. But there was one point gained that would prove of incalculable importance—the aetiology of the disease being known, we could, in a measure, protect ourselves from tuberculous infection. Care ought to be taken to prevent the sputa of consumptives from becoming dry and pulverized. It was dangerous to sleep in the same bed with a consumptive. Double beds ought to be discarded on general hygienic principles. People ought to be made aware of the existence of the disease. It did not benefit a patient or a patient's family to conceal the truth, especially since the dissecting-table had revealed the fact that many patients recovered from phthisis. A well-founded hope of ultimate recovery might therefore be held out to patients. Carpets in a sick room were dangerous under all circumstances, but especially were they so in cases of zymotic disease, above all in consumption. In hotels and buildings of a public character carpets ought to be abolished, because it was impossible to control their cleanliness and freedom from tubercular material. Raw beef should never be eaten, and milk should not be used in its raw state. Aside from certain diseases known to create a predisposition to consumption—measles and whooping-cough for instance—insufficient and unwholesome food, overcrowding, debauches, and want of ventilation and breathing space were all close allies of the disease. We could not prevent marriages between consumptives, although such marriages were in a sense immoral. Moral suasion and scientific conviction were equally ineffectual. It was a fact, as common as it was deplorable, that those were most eager to propagate their species who were least fitted for life and least likely to give rise to a healthy and vigor-

ous progeny. Again, there were the many depressing factors of our civilization, intimately connected and interwoven with our social, commercial, and industrial life, which all tended to pave the way for the invasion of the disease germ. To remove those factors would be to radically change our modern civilization—to realize the dreams of the most enthusiastic reformers—in short, it would be the establishment of the millennium. But much could be done to check and limit the disease by the means and precautions he had indicated.

Friday's Proceedings.

Officers for the Ensuing Year were elected as follows: Dr. JAMES E. REEVES, of West Virginia, President; the Hon. ERASTUS BROOKS, of New York, and Dr. HENRY B. BAKER, of Michigan, Vice-Presidents; Dr. J. B. LINDSEY, of Tennessee, Treasurer; and Dr. H. P. WALCOTT, of Massachusetts, Dr. CHARLES SMART, of the army, Dr. GEORGE B. THORNTON, of Tennessee, Dr. D. W. HAND, of Minnesota, Dr. GUSTAVE DEVRON, of Louisiana, and Dr. H. B. HOLBECK, of South Carolina, members of the Executive Committee. It was voted to hold the next meeting in Washington, in December, 1885.

Papers were read as follows: "On the Importance of Thorough and Complete Isolation in Scarlet-Fever Cases," by Dr. W. WINNEDGE, of Indiana; "The Administration of the Food and Drugs Adulteration Laws of Massachusetts," by Dr. B. F. DAVENPORT, of that State; "The Sources and Quality of the Meat and Milk Supplies of St. Louis," by Dr. SPIEGELHALTER, of that city, together with another on the same subject by Mr. J. C. CABANNE; "On Street Paving," by Mr. J. W. TURNER (by title); and "On the Climatic Conditions of St. Louis," by Professor F. E. NIPHER. A number of other papers were then read by title.

On motion of Dr. LISTON H. MONTGOMERY, of Chicago, a vote of thanks was passed to the President, Dr. Albert L. Gihon, for the able and impartial manner in which he had presided; and the meeting adjourned.

Miscellany.

THERAPEUTICAL NOTES.

Piscidia Erythrina.—According to the "Deutsche Medicinal-Zeitung," Fronmüller has made observations with this drug, using both the solid extract and the fluid extract, the former in doses of from two to four grains at bedtime, and the latter in doses of from seventy-five to two hundred drops. Sleeplessness was regarded as the indication for its administration. Ninety-three patients were thus treated, with most satisfactory results. The remedy is described as milder in its action than opium, as not constipating, and as having no influence upon the pulse, the temperature, or the secretions. In many of the cases sleep ensued after a half-hour, and was uninterrupted throughout the night. The patients awoke without a trace of heaviness or headache.

Paraldehyde.—Berger ("Breslauer ärztliche Zeitschrift") gives a short notice of this preparation, which he contrasts, as regards safety and efficiency, with chloral hydrate, much to the advantage of the former. The dose varies from three to six grammes, although one gramme has been mentioned as the proper limit. In order to disguise the extremely unpleasant odor and taste of the drug, the following combination is suggested:

Paraldehyde, gum arabic, each	18 parts.
Make an emulsion with distilled water	150 "
Add syrup of almonds	30 "

Dose, a tablespoonful, to be repeated in half an hour if necessary.

Pyrogallic Acid in the Treatment of Lupus.—Schwimmer ("Wiener med. Wochenschrift") states that mercury and pyrogallic acid exercise "a complementary and reciprocal action" when used at the same time in the treatment of this affection. The acid is applied in the form of an ointment (1 to 10), the inunctions being continued for eight days, and then suspended for two weeks, during which time mercurial plaster is applied. In general, the cure should be complete after two series of such inunctions. The duration of the treatment is usually from three to four months.

Papayotin.—According to the "Deutsche Medizinal-Zeitung," this comparatively new vegetable ferment acts as a digestive in either an acid, an alkaline, or a neutral liquid, and it is suggested as a valuable preparation for use in rectal alimentation. By reason of its solvent power, it has been employed as a local application in diphtheria. Diphtheritic membranes are rapidly dissolved by it, and the reporter (Finkle) expresses the greatest confidence in the drug for this purpose. The only efficient preparations have been imported from South America.

Pure Cannabine.—Bombelm ("Pharmaceutische Zeitung") describes the process of isolating the pure alkaloid by adding oxide of zinc to the tannate. The product is a dry, brownish-green powder, which is dispelled without residue by heating on platinum foil. Doses of from 0.05 to 0.1 gramme produce sleep without any preceding excitement. The pure alkaloid is tasteless, insoluble in water, but readily soluble in alcohol, ether, or chloroform. It may be administered in the form of powder, pills, or emulsion. When used in suppositories, all of its effects are obtained without the constipation produced by opium.

Lemon-Juice in the Treatment of Diphtheria.—Dr. Gartoyksi, of California, writes to the "Lancet" that he has long been accustomed to use fresh lemon-juice as the only remedy in the severest cases of diphtheria, a practice which he learned from the Chinese. The juice is drunk either in the form of lemonade or in the clear state. No statistics are given, but the author speaks highly of the benefit derived from this simple treatment.

Alcoholic Injections in Uterine Hæmorrhage.—Dr. Hapgood ("British Medical Journal") reports a severe case of uterine hæmorrhage where the only remedy at hand was a bottle of whisky. He promptly soaked a napkin in the whisky, and introduced it into the uterine cavity, with the result of stopping the hæmorrhage. Encouraged by his success, he states, he has now used injections of alcohol in several similar cases, and with such good results that he recommends this treatment to the consideration of the profession.

Sigmund's Mercurial Plaster.—The "Union médicale" gives the following formula:

Mercurial plaster,
Soap plaster, each, 30 grammes.

Mix at a moderate temperature and spread on fine cloth, not starched. This plaster is applied to syphilitic swellings, papules, vegetations, excoriations, and indurated testicles. It can be made into bougies or suppositories, which may be introduced into the urethra or the rectum in cases of syphilitic lesions.

Catarrh of the Bladder.—The same journal gives the following formula, used by Zeissl in the internal treatment of catarrh of the bladder:

Powdered leaves of *Herniaria glabra*,
Chenopodium, each, 5 grammes.

Mix and divide into five parts. Add one part to a litre of boiling water. The infusion may be made more agreeable by the addition of milk.

Collyria for Conjunctivitis.—The same journal gives also the following formula:

- | | |
|----------------------------|-----------------|
| (1.) Sulphate of zinc..... | 0.20 gramme; |
| Extract of opium..... | 0.10 " |
| Rose water..... | 30.00 grammes. |
| (2.) Sulphate of zinc..... | 1.00 gramme; |
| Powdered camphor..... | 0.50 " |
| Distilled water..... | 100.00 grammes. |

Stir until it dissolves, heating if necessary, and then filter.
These collyria are recommended in the catarrhal form of conjuncti-

vitis. They should be dropped into the eye three or four times a day, after the conjunctiva has been thoroughly cleansed.

The Inoculation of the Cholera Bacillus.—The "Wiener medicinische Wochenschrift" has a report from Berlin to the effect that Koch has succeeded in inoculating animals with the cholera bacillus, and in producing cholera in the rabbit; and, moreover, that Finkler and Prior's doctrine concerning the identity of the comma bacillus and the bacillus of cholera nostras has been found to be incorrect. Commenting on this statement, the "Gazette hebdomadaire de médecine et de chirurgie" adds the following: "Political journals inform us that Professor M. von Pettenkofer has declared publicly his readiness to ingest (*absorber*) Koch's bacillus cultures, and has expressed the hope that a large number of his colleagues will follow his example. We confess that we find it difficult to understand how a man of his position can lend himself to such romantic experiments."

The most Reliable and Sensitive Tests for Albumin.—An exhaustive paper on this subject, by Dr. H. B. Millard, in the "Medical Record" of May 31, 1884, founded on the results of numerous and extensive experiments with urine, artificially prepared peptones, dried serum and egg albumin, alkaloïds, etc., gives the following conclusions with reference to the tests for albumin: The author discards both Roberts's brine test and picric acid, the chief objections to picric acid being that, although it is a delicate test for albumin, like the brine test, it is objectionable from producing a precipitate with the parapeptones and all protein compounds. It is stated that these may be recognized by their clearing up on the application of a low degree of heat.

Dr. Millard, however, has not found this to be the case, either in peptonuria or in experiments with artificially prepared peptones. Picric acid also precipitates mucin, which may be known by its forming filaments upon the application of heat; that it forms precipitates with quinine and the oleo-resins is unimportant, as these disappear by heat or on the addition of alcohol. He has repeatedly found the brine test, used by Heller's method, to show a clear white line like that produced by nitric acid, where the existence of albumin could not be shown by any unmistakable tests. Nor does it offer any advantages over certain other absolutely positive and accurate tests described. The most reliable and delicate tests he believes to be in the order of their sensitiveness, *heat*, *nitric acid*, the *tungstate of sodium*, the *double iodide of mercury and potassium* (Tanret's test), and the *phenic-acetic acid* test, the last two, perhaps, being about equal in delicacy. *Heat* he considers the least sensitive of these, though Dr. Roberts professes to be able to detect 1 part in 250,000 of water. The urine should be clarified before using this test by filtration or boiling with liquor potassæ, and should be rendered faintly acid by adding acetic acid before applying heat. Dr. Millard used the heat test with serum albumin chemically prepared and with albuminous urine, but did not find it to show the presence of albumin in the slight proportion stated by Roberts. Nevertheless, if care is taken not to acidulate the specimen too much, heat is in many cases, perhaps in most, a good test. The author's experience, however, has been to the effect that it could be dispensed with in favor of the other four above mentioned.

The precipitate produced by *nitric acid* is not likely to be mistaken for anything but the urates, and these are easy of recognition. The test is not so sensitive, however, as the three following. It is valuable, however, because albuminuria so slight in degree as not to be shown by nitric acid is frequently, *ceteris paribus*, of but little practical importance, because there should be no difficulty in distinguishing the reaction produced by it from that produced by other substances, and finally because the thickness of the line or layer produced by Heller's method with it gives, according to Hofmann and Uitzmann's calculations, a very fair idea of the percentage of albumin.

The *tungstate of sodium* is entitled to high commendation. It is not caustic and does not stain, it is cheap and easily prepared, and is a more sensitive test than either of the preceding. Artificial peptones are precipitated by it but very slightly; it does not precipitate the parapeptones, and it gives no reaction with quinine. There seem to be no objections as regards its accuracy and freedom from reaction with other substances than albumin.

[It is employed in the same manner as Heller's test with nitric acid

—that is, by letting the urine trickle down upon a convenient quantity of the reagent placed in the bottom of a test-tube. It is prepared by mixing together equal parts of the saturated solutions of the tungstate (one part in four) and of citric acid (ten in six) and water. Thus prepared, however, it crystallizes or becomes turbid when cold. When this occurs, filtration should be employed, and the reagent will afterward remain clear.]

The double iodide of mercury and potassium, known as Tanret's test, is an exceedingly sensitive and satisfactory test.

The correct formula is:

Potassii iodidi.....	3.32 grm.
Hydrargyri bichloridi.....	1.35 grm.
Acidi acetici.....	20 c. c.
Aque dest. q. s. ad.....	100 c. c.

It may easily be prepared as follows:

"The 3.32 grm. of the iodide of potassium are placed in the bottom of a glass and a slight quantity more of distilled water than is necessary to dissolve the salt poured upon it; then in a second glass is placed 1.35 grm. of the bichloride of mercury, and a few drops of water are poured upon it, so as to produce a pasty consistence; then there is poured upon this gently down the side of the glass the contents of the first glass, taking care to agitate it constantly; the biniodide of mercury is immediately found manifested by an intense red. This mixture is stirred and distilled water added drop by drop till the redness has completely disappeared; the slightly yellowish liquid thus obtained is poured into 80 c. c. of distilled water, 20 c. c. of acetic acid are added, and the mixture is filtered. A liquid is thus obtained which is very transparent, almost colorless, and which can be preserved for a long time" (Capitan).

This test, used experimentally with diluted albuminous urine, dried egg- and blood-albumin, artificial peptones, and various alkaloids, is shown to be extremely sensitive and certain in detecting the presence of all protein substances. According to Capitan, 0.0035 c. c. of albumin to 1,000 grm. or one litre (about $\frac{1}{2}$ grain to a litre, or 1 part to more than 300,000) may be detected by it when all other reagents have ceased to show it. Of course, to detect the presence of such minute quantities of albumin, great care must be taken. It may be employed by placing the urine in the test-tube and letting the reagent trickle down upon it along the side of the tube by means of a pipette, when a cloudiness will result. On warming, this will remain uniform or resolve itself into flakes, according to the amount of albumin present. The best method, however, is to place the reagent first, and let the urine, which should be cleared if turbid, run slowly down the test-tube upon it. The two liquids thus remain separated, and at the point of contact a bluish disc is seen, more or less thick. The specific gravity of the reagent thus prepared is about 1.027. It is a good plan to mark the specific gravity of this and the tungstate on the labels, as where the urine is very heavy it will take its place at the bottom of the tube. It is important to recognize that other substances produce a reaction with this test resembling that produced by albumin; these are the urates in excess, peptones, quinine, and atropine—these are all readily soluble by heat and alcohol. The precipitate or cloud produced by morphine and strychnine with this reagent is not soluble by heat and alcohol when strong solutions are artificially prepared, but is soluble by heat in weak solutions, and would easily disappear in the minute quantities that would be likely to be found in the urine. All these precipitates, when dissolved by heat, reappear when the urine or solution containing them becomes cold. Mucin is also coagulated by this reagent, but, upon the application of heat, resolves itself into fine filaments. The existence of mucus is also easily recognizable with the microscope. Properly used, this test would appear free from error, and is certainly sensitive and simple.

The phenic and acetic acid and potash test is a modification by Dr. Millard of Méhu's test of phenic and acetic acid and alcohol. We give the author's own words:

"The proportions of the test as I have modified it are:

Acid. phenic. glacial. (96 per cent.).....	3 ij;
Acid. acet. puri.....	3 vij;
M. Acid. liquor. potasse.....	5 ij. 3 vj.

"It is important that the glacial carbolic acid should be used, or the mixture, which should be quite clear, will be turbid. Thus prepared, I find the test a perfectly satisfactory one. Where the two acids are used without the potash, I presume that an acid albumin is formed, which is prevented by the addition of the potash.

"This test appears to me, from my own experience, to be as sensitive as Tanret's, and perhaps more so, and, like it, produces no reaction with other substances than albumin that can not be easily accounted for. In a number of instances where Roberts's muriated brine test and picric acid showed parapetones manifested by disappearing by heat after Tanret's test, this showed no reaction.

"It forms a precipitate with artificially prepared peptones and with strong solutions of quinine, both easily soluble by heat and alcohol. With strychnine it presents no reaction except in strong solution, when it produces a slight cloud, and this readily disappears by heat. With strong solutions of atropine and morphine it produces a reaction, the precipitate being soluble by heat when diluted. These alkaloids would not occur in the urine in sufficient quantity to produce a reaction. I have produced slight opacity or turbidity in urine with this test, in which albumin had been shown by all the other tests I have mentioned, but, when the urine was greatly diluted, all except this one failed to give a reaction. Like Tanret's test, when albumin is present in minute quantities, as 0.005 grm. or 0.0035 grm. to the litre, it does not form a disc, but produces a loss of clearness, the opacity being of a slightly yellowish or greenish tinge, the cloudiness produced by Tanret's test being slightly opalescent."

Méhu's test has this insuperable objection, that, when the precipitate or cloud is subjected to heat to determine if it is albumin or peptone, it disappears. With the test as modified by Dr. Millard, however, the parapetones disappear by heat, but the albumin is unaffected by it.

"To sum up, then," the author continues, "I believe that in the double iodide of mercury and potassium, the tungstate of sodium, and phenic-acetic acid test, we have three reagents which combine the desiderata of extreme sensitiveness, accuracy, and simplicity. The phenic-acetic test has the advantage over Tanret's that it shows no reaction with quinine, and, if I adhere somewhat preferably in my examinations principally to the latter, it is because it has served me so well; it is perhaps good enough, but it is of importance to know that the phenic-acetic test seems equally good.

"As to heat and nitric acid, I use them sometimes; they are less delicate than the others, and I believe the former could be dispensed with entirely, as it is sometimes troublesome with acid-albumin or alkali-albumin. The nitric acid has the advantage of showing approximately the percentage of albumin, and its indications are positive.

"I can not see, if I am correct in my observations, that there should be the embarrassment that is alleged to exist in the selection of reagents for the detection of albumin with care and certainty."

Mosquitoes and Yellow Fever.—"The following propositions," says the "Lancet," "which give in a condensed form the chief conclusions of Dr. Carlos Finlay's work on yellow fever, deserve consideration. Ordinary yellow fever is inoculable by means of the bite of the mosquito (*Culex mosquito*) on the third, fourth, fifth, and sixth days of its natural evolution. The disease can not be transmitted by the agency of the insect before the third day or after the sixth, no matter what the severity of the disease. The period of incubation of this experimental inoculation varies as widely as that of natural yellow fever. The duration and severity of the fever produced by inoculation by the mosquito appeared to be proportional to the number of the bites, and presumably to the quantity of matter contained in the insect's fang. The inoculation with one or two bites of the insect has never been followed by phenomena other than those usually met with in benign yellow fever. The results obtained up to the present lend hope to the suggestion that the inoculation by means of one or two *piques* of the mosquito may confer immunity from the severe forms of the disease to those who have to dwell in its midst. The inoculability of the disease by the agency above indicated points to the value of guarding patients suffering from yellow fever against the bites of mosquitoes in order to prevent the spread of the malady."

Lectures and Addresses.

AN ADDRESS IN

OBSTETRICS AND GYNÆCOLOGY,

DELIVERED AT THE FIRST ANNUAL MEETING OF THE NEW
YORK STATE MEDICAL ASSOCIATION,
NOVEMBER 19, 1884.

By T. GAILLARD THOMAS, M. D.,

CLINICAL PROFESSOR OF DISEASES OF WOMEN IN THE COLLEGE OF PHYSICIANS
AND SURGEONS, NEW YORK.

MR. PRESIDENT AND GENTLEMEN—FELLOWS OF THE NEW YORK STATE MEDICAL ASSOCIATION: If I interpret aright your wishes in requesting from me an address on obstetrics and gynæcology on the occasion which brings you together in this city to-day, you desire, at the hands of one who has paid more attention to these subjects than the general reader and practitioner, an estimate from his standpoint of the present status of these departments of medicine, their relations to other branches, the advances which the past decade has accomplished for them, and the most signal lines of progress which have been pursued in the accomplishment of such advancement. If my conception of your wishes is correct, my task will not prove a difficult one, nor shall I be forced to weary you with prolix and uninteresting details.

Pardon a passing reference to the infancy of the science of obstetrics, which will serve merely to remind you of facts which you know as well as I do. Obstetrics as an art must always have existed, even among savage nations, and, as civilization and refinement have increased, this art has ever become more and more perfect, keeping pace, as other arts have done, with the general advance in a people's knowledge. And thus it is that obstetrics, advancing from the ages of the past, from the period of the wonderful old man of Cos to that of Smellie and Levret, existed as a very perfect art indeed. But it was in no wise a science. He who was to elevate it to this high sphere was found in the person of the great Englishman, William Hunter, whose admirable work upon the gravid uterus did for this department of medicine what the eminent labors of Euclid did for mathematics, and which exists to-day as a valuable part of the library of every intelligent practitioner of midwifery.

From that time to the present a steady advance has been made, and in our day we see the reproach which once upon a time, and that not so very long ago, attached to the "man-midwife" entirely wiped away.

But all this has often been written of; let me leap over the wide chasm which divides two centuries from each other and speak of those improvements in this hundred-year-old science to which the past decade has given birth.

With how little pomp and parade are the greatest discoveries of science usually heralded! Who could have pictured to himself the wonderful results which were to follow the crude experiments of Count Rumford with steam; the watching of the swaying of a set of church lamps by Galileo; Newton's study under the apple-tree; or the flying of a Yankee printer's kite upon Boston Common? Yet the world has trembled and swayed under the results of these

things, and mankind has felt their influence in every fiber and atom! In my judgment, one of the greatest achievements of modern pathology has been the discovery of the agency of certain lowly organized monads, micrococci, and microzymes, classed under the head of bacteria, in the production of septicæmia, pyæmia, and the long list of diseases which are their outcome. These atomic bodies, floating in the atmosphere, clinging to sponges and towels, and adhering to instruments and fingers, enter the blood through the open mouths of abraded surfaces. The prevention of the evil consequences of such entrance by the plans of Lister has accomplished a great deal for general surgery. Applied to obstetrics and gynæcological surgery, the same methods are found to be fully as successful.

Progressive obstetricians are now pretty well agreed that the diseases which follow child-birth are due, for the most part, to the introduction of some contagium or poisonous element from without through the open mouths of exposed blood-vessels, laid bare by the parturient process, somewhere between the fundus uteri and the vulva. This theory once being accepted, it follows as a natural deduction that every means in the power of the obstetrician should be adopted for the prevention of the introduction of the morbid agents.

Even although the obstetricians of to-day are not prepared to make aseptic midwifery a rule wherever that art is practiced, it is highly probable that in the very near future this position will be accepted. Even now this method, in modified form, is exerting a beneficial influence and steadily working its way to adoption in spite of the fact that it entails a good deal of trouble on the practitioner. That it can do no harm is quite evident. Does any man, can any conscientious obstetrician, maintain that strict cleanliness and the most scrupulous avoidance, so far as it lies in his power, of all things which can possibly admit of the entrance of the agents which in all probability produce puerperal septicæmia will do any harm in the lying-in chamber? Supposing that only one life is saved out of a hundred deliveries, will any one assert that the saving of this one life would not repay him for the trouble which his preventive precautions have cost him? If the whole theory of the bacterial origin of puerperal fever is false, then in a quarter of a century from now all precautionary measures will disappear and the old *régime* will triumph. But if, perchance, this theory is valid and true, then no human power will prevent the realization of the prophecy that aseptic midwifery will be a rule as strict, as inviolable, and as obligatory as the aseptic surgery of amputations and of laparotomy is to-day. Look at the surgery of London, of Paris, of Vienna, and of New York of twenty years ago, with its unclean hands, its fatally dirty instruments, its death-laden sponges, and its foul air, with its terrible mortality, and then look at the surgery of those same cities to-day; and he will be a bold man who dares gainsay the statement that in another quarter of a century no one will venture to rise in a scientific body and declare that any efforts at perfect cleanliness in the lying-in room are superfluous or absurd.

To free the parturient act from the dangers of septic

poisoning, to prevent that scourge, the so-called puerperal fever, suppurative arthritis, pyæmia, embolism, and septic inflammation of the lungs, liver, and other organs, would be to save millions of lives in every generation, and to raise the science of obstetrics to an enviable height.

The germ theory has done more for obstetric medicine than what I have here alluded to. It has revolutionized the treatment of that variety of septiciæmia which has been called puerperal fever. No longer do we depend in the treatment of this affection upon quinine, opium, and the application of emollients over the abdomen. By intra-uterine injections the cavity of the uterus is thoroughly and repeatedly washed out with solutions of the bichloride of mercury 1 to 2,000, or with a 2½-per-cent. solution of carbolic acid. Surely no one who has experience in the new and the old methods will cavil at my statement that a great improvement has been effected by the former.

Were I called upon to sum up the treatment of a *declared undoubted* case of puerperal septiciæmia, marked by the usual symptoms of pulse of 120, temperature 105° or 106°, which would meet the requirements of our time, I should give it categorically thus:

1. Quiet all pain by morphine hypodermically.
2. Wash out the uterine cavity with antiseptics.
3. Lower the temperature at once below a hundred, not by the barbarous method of the cold bath, but by the far better one of the coil of running water.
4. Feed the patient upon milk and nothing else, unless some good reason exists for changing it.
5. Exclude from her room all except the nurse and doctor, keeping her as quiet as possible.

Although the subject of extra-uterine pregnancy has attracted attention from the earliest days of medicine, it is only of late years that it has been carefully studied, its diagnosis put upon a firm basis, and its treatment systematized. Laparotomy, with its wonderfully beneficent results, has been brought to bear upon these cases before and even after rupture of the vicarious fetal nest. By this procedure Jessup, of England, has succeeded in delivering at full term a child developed in the peritoneal cavity and saving at the same time the mother; and by it Tait, of the same country, has saved four women after the fetal sac has ruptured. But it is to the feticide powers of the electric current, first used by Allen, of Philadelphia, and then by Landis and Reeve, that the safety of such cases can best be trusted. This method is harmless to the mother, even if an incorrect diagnosis be made, and effectual in producing fetal death if the diagnosis be correct. The number of lives which have already been thus saved is quite large, and is daily increasing. And these are lives which in former times would have been sacrificed to inattention, or want of power in diagnosis, or a lack of reliable remedial measures, even if diagnosis were rendered pretty certain.

It must not be supposed that in the olden time no cases of extra-uterine pregnancy were saved. In making my statement I allude only to the systematic management of cases in their early periods, both as to diagnosis and treatment. In this country, even as early as 1759, Dr. John Bard successfully performed gastrotomy for the removal of

a full-grown child from the peritoneal cavity. Dr. Baynham did so twice—once in 1791 and again in 1799; and Dr. John King, of Edisto Island, South Carolina, in 1816, cut through the vagina at full term, applied the forceps through the opening, and safely delivered a slave woman of a child which was developed in an abdominal pregnancy. But at that time and long afterward—until our own times, I may say—the early diagnosis and early treatment of tubal pregnancy were found to be impossible. To-day, given a woman whose symptoms of pregnancy are irregular, who suffers pain in one iliac fossa, who has sudden gushes of blood, and who is subject to occasional attacks of faintness, and every intelligent practitioner would at once examine with reference to the existence of ectopic gestation, and, discovering it, would promptly proceed to destroy the fœtus in its false uterus.

Some one has very pithily said of late that the medicine of a hundred years hence will consist chiefly of prophylaxis and surgery. It appears to me that the statement, which has more than one grain of truth in it, applies with great force to our subject of to-day. The day is, I feel sure, not far distant when preventive measures will be applied with a most triumphant result to placenta prævia, puerperal nephritis, placental apnœa, contracted pelvis, the obstinate, and often fatal, vomiting of pregnancy, and that extreme hydræmia which so often results in thrombosis.

Obstetricians are beginning to question themselves as to whether it is wiser, in the interests of both child and mother, to wait and watch during the last two months of pregnancy until a sudden and furious hæmorrhage makes an issue unavoidable in placenta prævia, a convulsion announces the point of tolerance in puerperal uræmia, or the cessation of foetal movement tells the tale that the crippled intra-uterine lung has ceased to have power enough to prolong foetal life. The methods of inducing premature labor are now so simple, so certain, and so void of danger that they, more than at any previous time, present themselves as a sovereign resource in such cases.

And this is more especially true since Tarnier, by his glass-house with heated air regulated so as to meet the feeble heat-making process of the premature infant, renders the perpetuation of the lives of these beings so much more certain than when they were exposed to the chilling draughts of the chamber, and perhaps were at once dipped in water and exhausted by washing and dressing.

How often has every man in this room watched with intense interest and anxiety the following picture! A mother of several children, a beloved wife, and the center of a large circle dependent upon her for love, for care, and for counsel, about the end of the seventh month develops the symptoms of placenta prævia, or severe puerperal nephritis. The physician can not conceal from those who surround her the fact that a violent hæmorrhage or sudden convulsive seizure may at any moment destroy life. Should one of these occurrences take place, the patient's friends know full well that it may be hours before medical aid can be obtained in their dire necessity. Day after day the painful process of watching, hoping, dosing goes on; and gradually the symptoms grow worse until the final issue comes

and great joy is felt if, the child being sacrificed, the mother survives. It is to save all this, at the expense only of exposing the child to the danger of premature birth—a child, too, whose life would be at great hazard even if the pregnancy were allowed to proceed—that premature labor offers itself as a valuable resource.

The obstetric forceps is probably the most life-saving instrument which surgery has ever invented; and from the time of the Chamberlens, about 1647, thousands in every generation have endeavored to improve it, thousands have handed down their names in connection with it by suggesting trivial modifications, and thousands have in their efforts rendered themselves butts for the laughter of their successors by reason of the vanity which guided them. Few, very few, real improvements have been made in these instruments, and these improvements have occurred at long intervals. The Chamberlens used short, straight forceps; Levret and Smellie added length and gave a pelvic curve to these, and nearly, if not quite, doubled their value; and Tarnier, of France, has, in our day, added a pair of tractors which enable the operator to pull more accurately in coincidence with the superior strait, while the handles are still in the inferior. This is the only real improvement in these instruments since the days of Levret and Smellie, and, like theirs, it marks an era in the history of the instrument, and a mile-stone in its advancing usefulness. There are cases, many cases, in which it is not called for; there are some, and not a few, in which it gives great facility in delivery.

Of late two substitutes have been proposed for the Cæsarean section—extirpation of the gravid uterus and its annexa after delivery of the child from it, or Porro's operation; and delivery of the child above the superior strait of the pelvis by cutting through the abdominal walls and vagina, or laparo-elytrotomy.

R. P. Harris, of Philadelphia, the only great medical statistician that America has yet produced, reports, in October, 1883, that the combined Porro and Müller operations saved, out of 116 cases, 48 $\frac{2}{3}$ per cent. of mothers, and 90 out of 118 children. Garrigues, in an able and exhaustive essay, reports in the same year that, out of eight operations, laparo-elytrotomy saved half of the mothers and all of the children except two, who died before the operation was undertaken.

In general terms, I think that, to state the comparative success of the two operations, it must be said that the results of laparo-elytrotomy have thus far been superior to those of the Porro-Müller operation, but that for some inexplicable reason the latter has found favor with the profession, both in this country and in Europe, which the former has failed to obtain.

From my experience with laparo-elytrotomy, I feel certain that, if a fair trial is given to it, it will surely yield a success greater than either the Cæsarean section or the Porro-Müller operation. It is so easy of performance, inflicts so little injury upon important viscera, and has already proved so successful, that I can not doubt its merits.

We must not conclude that, because the general professional mind is not favorable to an operation which has been little tried, such an operation has "been weighed in the

balance and found wanting." The following examples will prove the contrary: In 1834, Gossett, of London, discovered the present operation for vesico-vaginal fistula—position, metal suture, speculum, and all—operated twice, and published his operations. Yet it was left for Marion Sims, in 1852, to rediscover the whole matter. The greatest advance which has been made in medicine during the present century is the application of clinical thermometry, and its adoption is, as you all know, quite recent. Yet, about one hundred years ago, Currie, of England, fully developed this invaluable contribution to scientific medicine merely to see it pass out of notice and yield no results. And these are by no means the only instances of want of appreciation which can be quoted. I do not, therefore, despair of laparo-elytrotomy, but, from my personal knowledge of its advantages, am very hopeful of its future.

A little over a month ago Dr. Pilcher, of Brooklyn, having under his charge a case of labor in a deformed woman, aged twenty-one years, in good health, but with a rachitic pelvis, giving in its antero-posterior diameter of the superior strait a measurement of two inches, sent for Dr. Skene to aid him. After she had been in labor eight hours, Dr. Skene, with his well-known skill, performed laparo-elytrotomy and delivered her of a living child. To-day both mother and child are perfectly well, the after-history of the former being entirely uneventful, the wound healing by first intention, and the patient sitting up on the twenty-first day. It gives me great pleasure to avail myself of Dr. Pilcher's kind permission to report this, as yet unpublished, case to you to-day. And now in all candor let me ask you if a procedure which has effected such a result repeatedly, both as regards mother and child, should not be at least fairly tried before it is cast aside among the failures of obstetric surgery.

From the earliest records of the medicine of Egypt, of Greece, and of Rome, the practice of gynæcology can be readily traced, and although, like all other learning, it became paralyzed by the baneful influence of the dark ages, it was upon the revival of letters at once pursued. Before the middle of the present century, however, it did not in any respect deserve the name of a science. About that time, through two influences—the speculum, which since the days of Récamier had slowly worked its way into use, and anæsthesia, which enabled the surgeon to perform operations, both tedious and painful, upon the genital organs—the science of gynæcology passed in great degree out of the domain of medicine, with its uncertain theories and doubtful resources, into that of surgery. And from that day a new era has existed for this department of medicine which has given it a place among others, not only of respectability, but of dignity.

I know not what view others may take as to the influence which has had so great a result upon gynæcology as all have seen exerted during the past quarter of a century, but, in my judgment, it is the bringing into the service of the department the powerful aid of surgery. Let me beg you to observe that I am not urging the claims of surgery at the expense of those of constitutional treatment in gynæcology. Far from doing this, I am a strong advocate for

the great advantage of constitutional treatment in diseases of the pelvic viscera of the female. There is no more clashing between medicine and surgery here than there is elsewhere; they should work together for good, the one sustaining and supplementing the other. Nevertheless, I fearlessly assume the position that an enlightened, conservative surgery is the pivot around which is to revolve the gynæcology of the future, and that, were surgery withdrawn from this department to-day, it would be emasculated of the greatest part of its usefulness and efficiency, and would gradually lapse into the condition which it occupied a century ago.

Every virtue has a vice which so closely corresponds to it, and so nearly resembles it upon superficial examination, that the real and the false are often confounded. Vanity often simulates modesty; cold policy passes current for charity; even arrogant pride is not rarely mistaken for humility. In medicine, cant, for there is cant in medicine as there is in religion, in politics, and in all other spheres in which the mind of man works, is often mistaken for that most laudable and meritorious of medical qualities, conservatism.

When vaccination was introduced, a great deal of medical cant was talked; and so when the pains of labor were first assuaged by chloroform; when ovarian tumors were submitted to laparotomy and thousands of valuable lives were yearly saved; and so, also, when the obstetric forceps was put upon its proper basis as an instrument to be resorted to in the interest of mother and child, before the symptoms of powerless labor had absolutely developed themselves. When, through the instrumentality of Simpson, Sims, and Simon, surgery was introduced into gynæcology, a jeremiad was inaugurated, the echoes of which are only now dying away like the grumblings of a recent storm. Those who practiced gynæcological surgery were accused of recklessly mutilating the most beautiful of God's creation. Their conservatism was impeached, their judgment was impugned, their honesty was attacked. And what has been the outcome of the controversy, what is the present status of the moot question? By the aid of gynæcological surgery thousands of women, who formerly filled beds of suffering throughout their menstrual lives, are now in a month or two restored to perfect health; thousands who were doomed to early death are saved; thousands who for weary years visited the offices of one, and then another, and still another physician, resisting the powers of general tonics, and nitrate of silver, and potassa fusa, and the actual cautery, are now quickly enabled to perform all the duties of life without exhausting their resources by yearly stipends to the medical man. A woman suffers from profuse leucorrhœa, and backache, and difficult locomotion. Formerly she would have gone, times without number, to her doctor's office to have caustics applied to the ulcer of the neck of the womb, until he got tired of her or she of him. Now a lacerated cervix is cured by Emmet's great operation, and a limit is put to her patience and her husband's capacity to bear expense. A young woman, whose terrible sufferings at menstrual periods have half crazed her, made her nearly an opium-eater or gin-drinker, and almost transformed her

into one of those social vampires who suck the sympathies and vital force of a whole family in place of blood, instead of living on, a libel upon her sex, is cured by Battey's operation and restored to her place in life. Another, who has had the accident of lacerated perineum inflicted upon her by parturition, instead of passing her life in "ringing the changes" upon all the varieties of pessaries known to art, is cured by perineorrhaphy or colporrhaphy. And still another, who, perchance, for twelve years has had an issue of blood and who has suffered many things of many physicians, and has spent all that she had and was nothing bettered, but rather grown worse, after having exhausted all the hæmostatics and oxytocics and astringents, has a loop of wire, called a curette, carried into the uterine cavity, and fifteen or twenty fungoid growths, about as large as grains of barley, removed, and straightway the fountain of her blood is dried up.

Surely the time is at hand when the gynæcological surgeon may boldly say to his detractors, "Enough of this, the logic of events condemns your futile efforts"; and to those in his own department, "He who is not prepared to give his patients the advantages of surgery, either at his own hands or those of another, is not prepared to act honestly and fairly by those who intrust their interests to his keeping."

The pathological conditions which most frequently result in that chain of symptoms which mark the pelvic diseases of women may, I think, be fairly tabulated in the following manner:

1. Injuries received during parturition.
2. Natural or acquired imperfections of the uterus and ovaries.
3. Displacements of the uterus.
4. Benign neoplasms in the uterus, ovaries, or annexa.
5. Tubal and ovarian diseases.
6. Uterine catarrh.
7. Hyperplastic development of the endometrium.
8. Neuroses, such as vaginismus.
9. Inflammatory disease of the pelvic areolar tissue and peritoneum.
10. Malignant disease of the uterus or ovaries.

It may safely be said that in almost all of these a resort to surgical interference is often an essential to cure, while in most of them it is absolutely so.

No surgical procedure has more profoundly excited the interest of gynæcologists during the last decade, and I may add that none has done more good, than the operation of trachelorrhaphy. That its future sphere of usefulness is a large and brilliant one no one who has studied its results without prejudice at the bedside can for a moment doubt. May its originator long live to enjoy the evidence of the good which his labors have accomplished, and will continue for all time to effect.

Extirpation of the ovaries for three purposes—1, for effecting a premature menopause; 2, for checking the growth of large fibroids; and 3, for removal of ovaries and Fallopian tubes for hydro- and pyo-salpinx, and resulting pelvic inflammation—has now become a well-recognized and accepted resource in gynæcology. The originators of

these operations, for they really differ from each other in many essential respects, are Battey, Hegar, and Tait. So great are the benefits resulting from these procedures in the various conditions for which they are practiced that nothing can now stop their advance.

Nevertheless, as I look to-day into the future of any operation for removal of the ovaries, I see it the instrument of great abuse; I see it performed in numerous cases of mental disorder aggravated by the menstrual molimen in which it will fail of result; in many of uterine disease which could without its aid have been cured by care, patience, and skill; and in a great many cases in which diagnosis is obscure, and in which a resort to it is, to say the least, empirical. But I see opening before it, in the future, also a wide, very wide, field of usefulness; I see cases of women, doomed not only to misery themselves, but dooming whole families to life-long discomfort and anxiety, entirely relieved by it; and I see many instances in which without it the curses of opium-eating and dipsomania, which frequently ingraft themselves upon the monthly recurring dysmenorrhœa, lifted by it from moral death to lives of happiness. Are we to reject agents capable of great good because by misdirection they are likewise capable of great evil? No; let us hail the good and apply it to man's wants, and let us strive as best we may to limit and control the evil which we can not wholly avoid. No one can doubt that numberless evils have attended upon the discovery of gunpowder, yet no one can be blind to the fact that that discovery has done a vast deal for the advancement of civilization and the best good of mankind.

Even as early as the year 1560 Andreas à Cruce is said to have removed the uterus *per vaginam* for carcinoma uteri, and it is probable that even before his time Soranus had performed this desperate operation, which taxes in our day the skill, boldness, and resources of the surgeon. During the eighteenth century the operation was several times performed, and in 1813 Langenbeck had a successful case. In 1829 Récamier made improvements in it, and in 1878 Czerny revived the operation and placed it upon a firm basis. In 1883 Länger published the following statistics of the procedure:

Vaginal extirpation of cancerous uterus.....	133
Recoveries.....	95
Deaths.....	38
The percentage of deaths being.....	28

In 1884 P. F. Mundé published statistics of 256 cases, with a mortality of $24\frac{1}{2}\%$ per cent.

Freund, in 1878, revived the operation of the removal of the uterus by abdominal section, a procedure put in practice by Gutberlat as early as 1825. Freund's operation has now been performed 106 times, with a result of 72 deaths and 34 recoveries.

Not to detain you longer upon the present status of these two heroic procedures for desperate conditions, I would sum up the matter by the statement that Freund's operation, by reason of the great difficulties and dangers which attend its accomplishment, is now relegated to disuse; while vaginal extirpation of the uterus, although acknowledged to be a procedure of great danger, of undoubted

difficulties, and of questionable results, has conquered for itself the position of a recognized, legitimate, and even valuable, procedure.

An operation which ends fatally in one quarter of all the cases submitted to it is a procedure of questionable character, of course; but let him who feels disposed to question the justice of the estimate here given remember the terrible future which inevitably attends upon the progress of uterine cancer; the physical suffering, the mental distress, the disgusting concomitant circumstances, and he must admit that any operation which has the power, even at the imminent risk of death, to lessen or remove these, should be hailed as a precious resource!

Uterine extirpation for cancer, however, is one of the most difficult and dangerous of the resources of surgery. As a compromise measure, removal of the entire neck by a conical section extending even up to the fundus uteri, and subsequent closure of the cervical lips by suture, often supersedes it with great advantage.

Deformities of the uterus which alter its shape, impair its nutrition, and interfere with the perviousness of its canal, have long been recognized as grave pathological factors; and even in our day the most sanguine practitioner must admit that their treatment is difficult, uncertain, attended by the dangers of cellulitis and peritonitis, and unsatisfactory to a lamentable degree.

At the present day there are three methods by which uterine deformities—antelexion, retroflexion, and lateroflexion—are treated: First, the misshapen organ is repeatedly forced into better form by the introduction of the uterine sound, and subsequently it is in a lame, uncertain fashion sustained by a vaginal pessary; second, the tortuous cervical canal is cut at the internal and external os, and a uterine stem is introduced and kept in place by a sustaining vaginal cup; and, third, the whole uterine canal is at one sitting distended by a powerful "divulsor," or expanding forceps, to as great an extent as the tissue of the organ will bear. The first two of these methods are well known to you; it is the latter that I would now bring to your notice.

The heroic nature of this operation, its apparent brutality, and the dangers which one would naturally fear as a consequence of the forcible stretching of uterine tissue, which is really equivalent to absolute tearing of it, has retarded its advance to the position of an accepted operation. Its introducers and chief indorsers have been Priestley, Borek, Ball, and Ellinger, all of whom have claimed for it not only excellent results in cases of uterine deformity, but also a very marked immunity from the accidents which one would fear from it. In this city Dr. W. Gill Wylie has reported very favorably of it; and Professor Goodell, of Philadelphia, has recently published a paper upon it which, with the strong indorsement of his name, will go far toward rendering it popular, and exciting others to a fairer trial of it than it has yet received. Personally I have no experience of it worth reporting, but I certainly feel it a duty to test the question of its use fully from the evidence which we now have before us.

In connection with my subject I would mention four drugs which have of late been introduced into practice, all

of which appear to me to possess sufficient value to warrant their special mention here. These are the permanganate of potash, and the fluid extracts of the stigmata and ustilago maidis, of the *Viscum album*, of the *Viburnum opulus* and *Viburnum prunifolium*.

Permanganate of potash, introduced by Sydney Ringer, of London, as an excitant of the menstrual flow, is, I think, the best emmenagogue which has yet been discovered. The stigmata and ustilago maidis, or ergot of corn, are, like the fluid extract of *Viscum album*, or mistletoe, excellent oxytocic agents, and replace the ordinary *Secale cornutum* very well, not only during labor, but in causing uterine contraction for the relief of metrorrhagia, uterine fibroids, subinvolution, etc.

The medicinal virtues of the *Viburnum opulus* and *Viburnum prunifolium* appear to consist in an influence of sedative character upon the utero-ovarian nerves. These drugs have been greatly lauded as preventives of threatened abortion, and remedies for the pains which attend disordered menstruation. Although in my experience they have fallen far short of the excellence which has been claimed for them, I feel sure that they possess a considerable degree of virtue.

Although the prolific theme which you have allotted to me, Fellows of the Association, would readily afford me material for a much longer address, the fear of taxing your patience admonishes me of the propriety of bringing my remarks to a close. In doing so, let me beg of you to accept my thanks for the kind attention which you have accorded me—an attention which has given zest to my efforts and rendered my task a pleasure instead of a labor.

Original Communications.

REMARKS ON THE DIETETIC TREATMENT OF DYSPESIA.*

BY AUSTIN FLINT, M. D., LL. D.

THE term dyspepsia is often used in a sense nearly or quite synonymous with the term indigestion. These two terms are defined in Dunglison's dictionary as equivalent. The French dictionary by Littré and Robin and the recent "Dictionnaire usuel" give to each term a distinct definition. In the "Real Encyclopædie," commenced in 1880 and completed in 1883, indigestion is not treated of as separate from dyspepsia, the former being considered as embraced in the latter.

The name dyspepsia, from its derivation, denotes an affection not necessarily involving indigestion. The name signifies difficulty of digestion. Now, digestion may be difficult, and attended by more or less suffering and disturbance of the nervous system, the digestive function, nevertheless, being duly and completely performed. Clinical observation shows that dyspepsia, in this sense of the term, occurs without indigestion, the latter term embracing the

various forms of disordered digestion. Cases are of frequent occurrence in which symptoms arising from difficult, or, as we may say, labored digestion, are unattended by symptoms that denote any perversion or incompleteness of the digestive function. It may be said, and justly, that dyspepsia is often associated with indigestion, and that the latter can hardly exist without the former; but the point which I wish to make at the outset of this paper is, that the term dyspepsia denotes an affection distinct from, and irrespective of, indigestion, the latter term being considered as denoting an affection characterized by such symptoms as nausea, vomiting, flatulence, acidity, and diarrhoea—symptoms which show the digestive function to be either perverted or incomplete. By late German writers the affection which it suffices to call dyspepsia is designated nervous or neurasthenic dyspepsia.*

In this brief paper I must be content with an enumeration of some of the symptoms which belong to the clinical history of dyspepsia. The local symptoms referable to the stomach are a sense of weight or of oppression in the region of the stomach after the ingestion of food. The abnormal sensations are sometimes of an indefinite, distressing character. There may or may not be tenderness on pressure in this region. Absolute pain is sometimes felt. These local symptoms are much diminished, and they may disappear when the stomach is free from ingesta. The appetite may be more or less impaired, but it is often not diminished, and not infrequently it is increased. Patients complain in some cases of what is vulgarly known as a sensation of "gone-ness."

The symptoms, aside from those which are local, as regards the stomach, relate especially to the nervous system. Patients are depressed, irritable, and hypochondriacal. There is lack of buoyancy, energy, and of both physical and intellectual endurance. Vertigo is a not infrequent symptom. Neuralgic pains in the head and elsewhere are common. Sleep is disturbed, or there is insomnia. Disordered action of the heart is of frequent occurrence. Constipation is the rule. There is undue susceptibility to cold. All these symptoms may be measurably explained, in many instances, by co-existing anæmia. The dyspepsia leads to impoverishment of the blood, often because alimentation is reduced below the needs of nutrition, and this condition tends in no small degree to increase the dyspepsia and render it persistent. The symptoms referable to the mind are, doubtless, in part secondary to the dyspepsia, but I have long held the opinion that the mind plays an important part in the ætiology of the affection.

In 1841 I contributed to the "American Journal of the Medical Sciences" a paper entitled "Dyspepsia as connected with the Mind." In that paper I described the mental disorders often associated with difficult or labored

* *Vide* articles by Leube and Ewart in "Verhandlungen des Congresses für Innere Medicin," Dritter Congress, Wiesbaden, 1884, together with a discussion by several members of the Congress. Leube has demonstrated the existence of nervous dyspepsia, without any disturbance of gastric digestion, by withdrawing the contents of the stomach at different stages of the process of digestion, and ascertaining, by the use of the stomach-tube, the duration of this process in the stomach of patients suffering from dyspepsia.

* Read before the New York State Medical Association, November 18, 1884.

digestion, and expressed the opinion that these disorders are not entirely effects of dyspepsia, and that the causes of this affection may be mental. This view of the aetiology was at the time novel, and, at the present time, is by no means fully recognized either in theory or practice.

I had been led to regard dyspepsia as, in many instances, referable to the mind, by personal experience. Notable distress attending the process of digestion, and accompanied by great mental depression, despondency, and apprehensions, followed a change from college excitements and pleasures to a comparatively solitary life in the country and the commencement of the study of medicine. Instantly on beginning to attend medical lectures in the city of Boston, and coincident with exuberant spirits, dyspepsia disappeared.

At the time when the paper to which I have referred was written, dyspepsia, in New England, prevailed very generally among the classes of society which may be distinguished as educated, or, perhaps, as may be better said, the reading and thinking classes. Exemption from this affection was an exception to the rule. The contrast between that time and the present time in that regard is striking.

How is this contrast to be explained? The explanation in part relates to the mind as involved in the causation of dyspepsia, and partly to dietetics.

A half-century ago most maladies were supposed to originate in the *primæ viæ*, as the digestive organs were significantly called. It was enjoined upon all who desired to preserve health to watch closely these organs, and to make a constant and careful study of diet with reference to digestion. Dietetics and digestion, next to the weather and politics, furnished the topics for common conversation. The evils of the gratification of the appetite for food furnished themes for writers and preachers outside of the medical profession. Moral as well as physical ills were referred to errors in diet, for which the sufferers were held responsible. There are a few at the present day who entertain those ideas which were so common fifty years since. Within a few months I have received a sermon by a clergyman in which a strictly regulated and spare diet is recommended as indispensable not only for health, but for good morals and religious faith.

The views generally entertained, at the time to which I have referred, largely by physicians and almost universally by non-medical sanitarians, may be summed up in a few maxims as follows: Eat only at stated periods—twice or thrice daily, never between meals, no matter how great may be the desire for food. Never eat late in the evening or shortly before bedtime. In the choice of articles of diet, carefully select only those which reason and personal experience have shown to be best digested; never yield to the weakness of eating any article of food simply because it is acceptable to the palate. In order to avoid the temptation of overeating, let the articles of food be coarse rather than attractive, and eschew all the devices of the cuisine. Always leave the table hungry. Study personal idiosyncrasies, and never indulge in kinds of food which, although wholesome for most persons, are injurious to the few who are peculiarly organized. With reference to this last maxim,

bear in mind that "what is one man's meat is another man's poison." In order to secure, as effectually as possible, a proper restriction in the quantity of food, it was recommended by some physicians, and to some extent practiced, that every article be carefully weighed at meal-times, and a certain quantity by weight never exceeded. Vegetarianism, or Grahamism, was advocated and practiced by many. Total abstinence from drink was considered by a few a good sanitary measure, compelling the body to derive the fluids needed exclusively from fruits, vegetables, and other solid articles of diet. Restriction in the amount of drink, as far as practicable with regard to the power of endurance, was very generally deemed important, so as not to dilute the gastric juice.

Dyspepsia formerly prevailed chiefly among those who adopted, to a greater or less extent, the foregoing maxims. It was comparatively rare among those who did not live in accordance with dietetic rules. The affection is much less prevalent now than heretofore, because these maxims are much less in vogue. The dyspeptics of the present day are chiefly those who undertake to exemplify more or less of these maxims. It seems to me, therefore, a fair inference that dyspepsia may be produced by an attempt to regulate diet by rules which have for their object prevention of the affection which they actually produce. It is to be added that an important causative element involved in the practical adoption of these rules is the attention thereby given to digestion. It is by introspection and constant watchfulness of the functions of the stomach that the mind exerts a direct influence in the causation of this affection.

The foregoing views of the aetiology of dyspepsia foreshadow the dietetic treatment. Considering the limits to which this paper must be restricted, I can perhaps best submit the general plan of treatment which I have for many years pursued by supposing a hypothetical case.

A patient presents the symptoms which denote difficult or labored digestion, with more or less of the associated symptoms which have been enumerated. We will assume the diagnosis to have been made positive by excluding gastric ulcer, gastritis, carcinoma, and other lesions of the digestive organs. Renal and cerebral diseases have also been excluded.

I am accustomed then to ask the patient, "Do you regulate your diet?" The answer is generally in the affirmative, and it is often given promptly and emphatically. Then I say: "This is a good reason for your having dyspepsia; I never knew a dyspeptic get well who undertook to regulate diet." The patient is usually not a little surprised at these assertions, and may take issue with them. The success of the treatment will depend on the willingness and confidence with which the patient enters upon a reform in dietetic habits. "What system of diet do you advise?" is a question which is naturally asked. The answer is, that I have no rigid system of diet to advise, but that food must be taken in sufficient quantity and sufficiently varied to satisfy the requirements of assimilation and nutrition, and that this is not to be done by adopting any fixed rules regulating the amount and the kinds of food. "How am I to be guided?" is a question which naturally follows. The reply

is: "Not by theoretical views of nutrition and digestion, no matter how much they may appear to be in accord with physiological and pathological doctrines, but by the appetite, the palate, and by common sense." The patient, if intelligent (as dyspeptics usually are), may be reminded of the fact that nature has provided appetite and the gustatory sense for the regulation of diet as regards quantity and variety. To oppose these natural regulations is to do violence to nature. If the patient is a clergyman, he may be taxed with a want of sufficient reliance on Providence. Providence or nature takes care of digestion, leaving only the claims of appetite and the palate for human oversight.

"But," the patient will be likely to say, "am I not to be guided by my own experience, and avoid articles of food which I have found to disagree with my digestion?" The answer is, that personal experience in dietetics is extremely fallacious. An article of diet which may cause inconvenience or indigestion to-day may be followed by a sense of comfort and be well digested to-morrow. A variety of circumstances may render the digestion of any article of food taken at a particular meal labored or imperfect. As a rule, articles which agree with most persons do not disagree with any, except from casual or accidental circumstances, and the expectation, in the mind of the patient, that they will disagree. Without denying that there are dietetic idiosyncrasies, they are vastly fewer than is generally supposed, and, in general, it is fair to consider supposed idiosyncrasies as purely fanciful. Patients not infrequently cherish supposed idiosyncrasies with gratification. The idea is gratifying to egotism, as evidence that Providence has distinguished them from the common herd by certain peculiarities of constitution.

Dyspeptics generally have many questions to be answered. They are proverbially long-winded in giving a history of their experiences, and inquisitive as regards information from their physicians. Supposing our patient to be a type of this class of patients, a full account of the matters discussed in a consultation would extend this paper to too great length. Suffice it to say that the maxims which have been enumerated as causative of dyspepsia are to be reversed in pursuing the plan of treatment which it is the purpose of this paper to submit. The instructions, abbreviated, will then be as follows:

Do not adopt the rule of eating only at stated periods—twice or thrice daily. Be governed in this respect by appetite; eat whenever there is a desire for food. Eat in the evening, or at bedtime, if food is desired. Insomnia is often attributable to hunger. In the choice of articles of diet, be distrustful of past personal experience, and consider it to be a trustworthy rule that those articles will be most likely to be digested without inconvenience which are most acceptable to the palate. As far as practicable, let the articles of diet be made acceptable by good cooking; as a rule, the better articles of food are cooked, the greater the comfort during digestion. Never leave the table with an unsatisfied appetite. Be in no haste to suppose that you are separated from the rest of mankind by dietetic idiosyncrasies, and be distrustful of the dogma that another man's meat is a poison to you. Do not undertake to estimate the

amount of food which you take. In this respect different persons differ very widely, and there is no fixed standard of quantity which is not to be exceeded. Take animal and vegetable articles of diet in relative proportions as indicated by instinct. In the quantity of drink, follow Nature's indication, namely, thirst. Experience shows abundantly that, with a view to comfortable digestion, there need be no restriction in the ingestion of fluids.

It is perhaps needless to say, but in justice to my subject it should be considered, that in these few remarks I have given but a rough outline of the dietetic treatment of dyspepsia, according to the general plan which for a long time I have advocated, and of the merits of which I am able to speak from not an inconsiderable experience. There are various incidental points of inquiry, and certain qualifications of statements, which a full consideration of the subject would embrace. The ground which I take is, that the diet which in healthy subjects is conducive to the preservation of health is the diet which is desirable in cases of dyspepsia. Restrictions of diet when digestion is difficult or labored, with a view to adaptation to a supposed diminished capability of the digestive organs, I believe to be never successful, and injurious in proportion as the restrictions involve diminished assimilation and nutrition. It is a fallacy to suppose that the digestive organs in dyspepsia need rest. Exercise of the functions of the different organs of the body tends to the maintenance of their functional capabilities. Some old writer said that the stomach was like a school-boy: unless kept pretty constantly occupied it was sure to get into mischief. If there is an important practical truth in this remark. If the stomach behaves perversely, like the mischievous school-boy, the patient should conquer the stomach, and not the stomach the patient. This simile may sometimes be used with advantage in order to make patients not afraid to rely upon their digestive powers.

This paper, on account of the limitation as to time, does not afford an opportunity for the introduction of reports of cases; were it otherwise, I could cite many illustrations of the success of the general plan of treatment which I have outlined. In some cases which have come under my observation, patients who had been chronic dyspeptics for many years found themselves at once cured by adopting a full and varied diet, following nature's indications and taking no thought of what they should eat or what they should drink, and occupying the mind with other topics than those relating to their digestion.

Finally, let us learn a practical lesson from our observations of the class who "live to eat"—the *gourmet* and the *gourmand*—they "who fare sumptuously every day." Dyspeptics are not common among this class. An overstimulated appetite may lead to other affections—such as gout, indigestion, fatty heart, etc.—but rarely to dyspepsia.

Let us learn another practical lesson from our observations of those who "eat to live"—the hard-working laborer or mechanic, who is satisfied with obtaining an ample supply of food, and who has no time to study, by his personal experience, the relations of diet to digestion. Our dyspeptic patients do not belong to this class.

Let us learn another lesson from our observations of the

classes to which our dyspeptic patients do belong. They are, for the most part, lawyers, clergymen, doctors, students, teachers, artists, bankers, literary men, and men of leisure. Of those belonging to these classes, they become dyspeptics who study, from the best of motives, how to live, as regards diet, so that "digestion shall wait on appetite, and health on both." And for this end they endeavor to regulate diet by watchfulness, personal experience, theoretical notions, or, perhaps, scientific principles.

Let a fourth lesson be learned by observing the results of the dietetic treatment of dyspepsia based on the conclusions to be drawn from the previous lessons.

FOUR SELECTED TYPICAL CASES OF DIABETES MELLITUS NOT BEFORE REPORTED.*

By AUSTIN FLINT, JR., M. D.,

PROFESSOR OF PHYSIOLOGY AND PHYSIOLOGICAL ANATOMY IN THE BELLEVUE
HOSPITAL MEDICAL COLLEGE, NEW YORK CITY.

In May, 1884, I reported fifty cases of diabetes mellitus to the "Section on Practice of Medicine and Materia Medica of the American Medical Association," and to this report, which is contained in the "Journal of the American Medical Association," July 12, 1884, I refer the Fellows of this Association for full details of the treatment employed. Since this publication, I have had under treatment four cases of diabetes, which are typical in many of their characters, illustrating different conditions of the disease and the effects of treatment in patients of different ages.

The first case, which, for my own convenience, I shall designate as No. LIII, illustrates the difficulties met with in treatment when the disease has been allowed to run its course without restraint for a number of months.

CASE LIII.—The patient was an unmarried woman, twenty-two years of age, rather slight in figure when in health, and of medium height. Her parents are living and in perfect health. The family history failed to show any hereditary tendency to this or to any other disease. When in health the patient weighed 140 pounds. This was the weight about three years before she came under my observation. As far as I can judge from the history of the case, the disease must have existed for two years, or perhaps longer. In January, 1884, the patient had lost about twenty pounds in weight, had excessive urination, an abnormally great appetite and thirst, and suffered from a feeling of exhaustion after moderate exercise. At that time she passed, as was stated, from six to eight quarts of urine in the day, which was loaded with sugar. Before the diabetes had become developed, she had enjoyed perfect health with the exception of dysmenorrhœa, which had existed since the age of eighteen. She began to menstruate at the age of thirteen, and at the age of eighteen fell from a wagon, striking on her feet, and sustaining no apparent injury at the time. Since this fall, however, she had persistent dysmenorrhœa, suffering intense pain for six or eight hours at every period. She has not menstruated since February, 1884; and in January and February, 1884, she suffered no pain. She was examined in October, 1884, by Dr. James B. Hunter, who found retroversion, but advised no interference unless menstruation should return.

* Read before the New York State Medical Association, November 20, 1884.

When the patient consulted me on August 25, 1884, she presented all the characteristic general symptoms of diabetes mellitus, including excessive appetite and thirst, weariness after slight exercise, some pruritus vulvæ, and an increased quantity of urine. Her weight was ninety-two pounds. During the winter of 1883-'84, and the summer of 1884, she had indulged excessively in starchy matters and sweets, and since January had taken various remedies without experiencing any benefit.

August 26th.—The urine of the twenty-four hours measured 159 fluidounces, was pale, of a sweetish odor, and had a specific gravity of 1.037. It contained 28 grains of sugar to the fluidounce, giving a discharge of 4,256 grains (8 ounces, 416 grains) in the twenty-four hours. There was no albumin. Microscopical examination revealed the presence of a few octahedra of oxalate of lime with some vaginal epithelium. She was at once put upon a strict anti-diabetic diet, all starch and sugar being rigidly excluded, and was ordered to take three drops of Clemens's solution of arsenite of bromine three times daily.

September 1st.—The quantity of urine was reduced to 112 fluidounces. The sugar was reduced to 12½ grains to the ounce, or 1,400 grains in the twenty-four hours. The excessive appetite and thirst and the pruritus vulvæ had disappeared. The dose of the Clemens's solution was increased to five drops. She felt better and stronger, and the weight (taken September 3d) was increased to 99 pounds.

10th.—The weight had increased to 103 pounds, and the quantity of urine was reduced to 96 fluidounces, with a specific gravity of 1.023½. The total discharge of sugar for the day was 1,152 grains. The urine, however, presented a trace of albumin. The treatment was continued, with the addition of two grains of quinine three times daily. She had slight uterine pains on September 8th, 9th, and 10th, this being the time in the month when her periods occurred, but there was no menstruation. There was no unusual thirst, and the appetite was normal. She bore the strict anti-diabetic diet very well.

24th.—The weight had slightly decreased, being reduced to 101 pounds. The quantity of urine was 80 fluidounces, with a specific gravity of 1.025, and containing in all 800 grains of sugar. Since September 10th she had been losing strength as well as weight. The treatment was continued, with the addition of one quarter of a pint of cream and a tablespoonful of whisky twice daily.

October 10th.—The weight was reduced to 96 pounds. The quantity of urine was 80 fluidounces, with a specific gravity of 1.023, and containing in all 720 grains of sugar. The patient had followed the treatment, dietetic and medicinal, most faithfully. She had taken, for about four weeks, griddle-cakes made of Hecker's farina, which contains only one or two per cent. of starch. Notwithstanding the rigid diet, however, I had been unable to reduce the quantity of sugar below 9 or 10 grains to the fluidounce of urine, or 700 to 800 grains in the twenty-four hours, and the strength and general health showed no improvement since September 24th. I decided to try to arrest the discharge of sugar by an absolute fast of twenty-eight hours—a method recommended by Cantani. To this plan the patient cheerfully assented. She accordingly fasted from 8 A. M., October 10th, to 12 M., October 11th, remaining in bed most of the time, and taking nothing but water. The urine passed at the close of the fast contained two grains of sugar to the fluidounce; but it presented oxalate of lime, a small quantity of albumin, and a few small, granular casts. She bore the fast very well, had a good appetite the next day, and for several days felt better than she had for weeks. Following the fast, the former treatment was resumed.

15th.—The quantity of urine was somewhat reduced. Its specific gravity was 1.030, and it contained nine grains of sugar to the

fluidounce. There was still a little albumin, with a few granular casts. The patient felt her health in general on the following day. She was in much better general health than when I first saw her on August 18th, but I had found it impossible to arrest the discharge of sugar.

My prognosis in this case is not entirely favorable. It is probable that the excessive indulgence in sweets and in starchy articles of food for several months during the height of the disease has rendered the glycosuria uncontrollable beyond a certain point. Her present safety undoubtedly lies in an anti-diabetic diet, and a return to sweets and starch would probably be promptly followed by a return of all of the grave symptoms of the disease.*

The following case is in striking contrast to the one just recited:

CASE LV. The patient was a young girl, of medium height and development, fifteen years of age. Her father and mother are living and in good health, and there is no hereditary tendency to disease. A sister of the patient died at the age of nineteen, probably of diabetes mellitus. The patient began to menstruate at the age of thirteen and has menstruated regularly ever since that time. She was in perfect health up to January, 1884, when she began to lose flesh slightly, and was "tiring" for a few weeks. She soon improved in general health and was apparently well until the middle of August, 1884, when she was found to be passing about two quarts of urine daily, the specific gravity of which was said to be 1.052. Since that time she has been on a moderately restricted diet and has taken various remedies. She suffered somewhat from thirst during August and September. Her urine was found sometimes to contain a little sugar and sometimes was free from sugar.

Observation.—I made a thorough physical examination of the patient and found no disease. The urine was rather less in quantity than normal, had a specific gravity of 1.031, and contained no sugar. The only abnormal condition of the urine was the presence of a large number of octahedra of oxalate of lime. The diet had been moderately restricted. I ordered that the diet be unrestricted for twenty-four hours.

10th.—After twenty-four hours of unrestricted diet, the quantity of urine was slightly increased. It had a specific gravity of 1.036, and contained thirty-one grains of sugar to the fluidounce. There were none of the characteristic general symptoms of diabetes. I ordered a strict anti-diabetic diet, three drops of Clemens's solution of arsenite of bromine three times daily, the dose to be gradually increased to five drops, and a pill of one quarter of a grain of codeine and one twelfth of a grain of podophyllin at night, to relieve constipation should it be present. The patient then left on her home in Virginia.

16th.—I heard from this patient and received a specimen of urine. The treatment had been followed strictly. She had felt perfectly well since her return to Virginia and was passing urine in normal quantity. The urine had a specific gravity of 1.015 and contained no sugar.

In this case the glycosuria seemed to be easily controllable. After examining the urine, I wrote to the friends as follows:

I suggest that the dietetic and other measures of treatment be strictly followed until the middle of December. If, at the

end of that time, the urine should continue free from sugar, the patient may begin to eat a little bread and gradually return to the usual diet, except that she should never eat sugar or sweets. The urine should be examined from time to time while she is in process of returning to the normal diet.

My prognosis in this case is favorable. With proper attention to the diet, I should expect a cure; but it will be necessary to examine the urine occasionally for a long time, in order to detect, at the earliest moment, any tendency to a return of the disease.

CASE LI.—This patient was a robust man, unmarried, thirty-four years of age, five feet seven inches in height, and weighed 177 pounds. He had always eaten largely of bread and sweets. For several weeks he had a moderate increase in thirst and had not been "feeling very well." His urine had been examined, and it was said to contain sugar. His previous health had been good. He had occasionally committed sexual excesses.

I examined this patient on April 8, 1884, and found no disease. The urine was somewhat less in quantity than normal, with a specific gravity of 1.035 and was turbid with urates. It contained no sugar. During the day on which this urine was passed, the patient had abstained from bread and sweets.

April 10th.—I examined a specimen of the urine passed during the day, the diet having been unrestricted. It had a specific gravity of 1.026 and contained a small quantity of sugar.

June 2d.—Since April 10th, the patient had followed a strict anti-diabetic diet and had taken three drops of Clemens's solution of arsenite of bromine three times daily. His urine had a specific gravity of 1.030, was normal in quantity, and contained no sugar. The patient felt perfectly well, but his weight had been reduced to 167 pounds. The dose of Clemens's solution was increased to five drops.

July 16th.—The patient was still perfectly well, the diet was not irksome, and the urine was normal, free from sugar, and had a specific gravity of 1.024. The weight had been reduced to 161 pounds. The treatment was continued.

August 1st.—The patient continued well, but the weight was reduced to 159 pounds. The urine was normal, free from sugar, and had a specific gravity of 1.029. The treatment was continued.

14th.—The patient continued well, and the weight had increased to 161 pounds. The urine contained no sugar and had a specific gravity of 1.026.

20th.—The patient continued in the same condition. The weight was 157 pounds, and he looked and felt in perfect health. The urine contained no sugar and had a specific gravity of 1.031. The patient then passed from under my observation. The Clemens's solution was stopped and he was instructed to gradually return to a normal diet, but never to eat sugar or sweets, and to carefully abstain from all excesses of any kind.

In this case, the patient being a young and vigorous man, the glycosuria was readily controllable, and an apparent cure was effected.

The fourth case is that of a man, fifty-nine years of age, in whom the disease, although not at least a year's standing, yielded promptly to treatment.

CASE LII.—The patient, a married man, fifty-nine years of age, was 5 feet 10 inches in height, and weighed 227 pounds. He was robust, had always enjoyed good health, and had been rather a free liver, but without excesses of any kind. The family history gave no evidence of hereditary tendency to disease. For the nine months previous to the time that he came under my observation, he had suffered from excessive urination, an-

*The following case is a further illustration of the fact that the glycosuria in some cases is not easily controllable. It is a case of a man, fifty-nine years of age, who had been suffering from diabetes mellitus for several years. He was a free liver, but without excesses of any kind. The family history gave no evidence of hereditary tendency to disease. For the nine months previous to the time that he came under my observation, he had suffered from excessive urination, an-

noying thirst, abnormal weariness, and impairment of appetite. During this period he had lost about twenty pounds in weight.

August 11, 1884.—I examined a specimen of the urine. Its quantity in twenty-four hours had not been measured, but was undoubtedly excessive. It had a specific gravity of 1.023 and contained considerable sugar with abundant uric-acid crystals. He was at once put upon a rigid anti-diabetic diet, with three drops of Clemens's solution of arsenite of bromine three times daily.

19th.—The general diabetic symptoms had entirely disappeared. The urine was normal, with a specific gravity of 1.020, and free from sugar. The weight was unchanged at 227 pounds.

26th.—The patient felt perfectly well. The urine had a specific gravity of 1.012½ and was free from sugar. The dose of Clemens's solution was increased to five drops.

September 28th.—The patient continued to feel perfectly well. The urine had a specific gravity of 1.030 and was free from sugar. The weight had increased to 235 pounds. The Clemens's solution was stopped, and the patient was allowed to eat a little bread.

October 11th.—The patient felt that he was entirely cured. His weight was 233 pounds. The urine was perfectly normal, had a specific gravity of 1.020, and was free from sugar. He was directed to follow a reasonable diet, not abstaining entirely from starchy matters, but avoiding sugar and sweets. He was directed to have his urine examined again in about six weeks.

The limited time at my disposal prevents me from giving the diet-table for diabetics and other details of treatment, which would be merely a repetition of what is contained in my paper on the "Treatment of Diabetes Mellitus," published in the "Journal of the American Medical Association," July 12, 1884, and in the sixth edition of my little book on the "Chemical Examination of the Urine in Disease." The diet-table is very varied and is not difficult to follow, the greatest hardship to patients being deprivation of bread. It is a curious fact, however, that, after following a strict diet for two or three weeks, diabetics lose their craving for prohibited articles of food, and the diet becomes by no means irksome. Bread made of Hecker's anti-diabetic flour and porridge and cakes made of Hecker's farina are sometimes much relished. These articles contain between one and two per cent. of starch and do not seem to be injurious. The patients, in all of the cases here reported, were in good circumstances and both willing and able to follow strictly the prescribed diet.

In presenting an account of these four typical cases to the Association, I have purposely put the unfavorable case first. This is the second case that I have met with in which, patients being willing to submit absolutely to treatment, I have not been able to arrest the glycosuria. In this case, for many months the patient indulged inordinately in sweets; and the disease, which was complicated by albuminuria, had become so thoroughly confirmed that, although the general symptoms were controlled, even total abstinence from food would not remove the sugar from the urine. In the three remaining cases, sugar never appeared in the urine after the first week of treatment. The effects of treatment in these cases and in others that I have reported lead me to repeat the quotation from Cantani that I have already made in the paper read by me before the Medical Section of the American Medical Association:

"Diabetes has become to-day a disease easily and certainly curable, provided that the treatment (cure) be not begun too late."

A NEW PROCEDURE IN PARACENTESIS THORACIS.*

By THOMAS F. ROCHESTER, M.D.,

BUFFALO, N. Y.

Those who have often practiced paracentesis thoracis in chronic pleurisy, and especially in empyema, have frequently experienced great difficulty in making a sufficiently large and free opening to admit of the proper placing of drainage-tubes, or even of inserting a good-sized trachea and cannula in the chest cavity. This is doubtless caused by the approximation of the ribs, from the influence of chronic pleuritis upon the intercostal muscles. To obviate this, various expedients have been resorted to, such as gradual dilatation with sponge tents, and even trephining or excision of a rib. The writer thinks he has hit upon a method which will overcome the contraction with certainty and safety, and will greatly facilitate all necessary local operations. Perhaps a brief narration of three cases will present the procedure more clearly to you than a simple description of the method.

CASE I.—In September, 1883, I was invited by Dr. Seeley, of Attica, to see Mr. P., a well-to-do farmer, forty-five years of age. He had been ill for three months. I found him sitting up—he could not lie down for dyspnoea; both legs and feet were much swollen; he had cough, with muco-purulent expectoration; had irregular chills and night-sweats; pulse 100 and irregular; no appetite; percussion resonance fair over entire posterior portion of chest; flat over anterior surface of right chest from second rib down, with bulging of intercostal spaces. Percussion resonance clear over left chest anteriorly, except over precordial region; heart apex in sixth intercostal region and two inches to the left of a line drawn through the left nipple; auscultation posteriorly, respiratory murmur, with occasional bronchial râles distinct everywhere; anteriorly, bronchial respiration in right subclavian region as far as third rib; elbow that no respiratory sound whatever; puerile respiration marked in left lung.

Diagnosis.—Sacculated empyema; a large and long hypodermic needle was passed between the fifth and sixth ribs, anteriorly, on the right side; the barrel of the syringe was filled with thick, white, odorless pus; paracentesis was decided upon; a sharp-pointed bistoury was inserted close to the upper border of the sixth rib, and an incision two inches long was made in the intercostal space; a very slight purulent discharge followed. We now proceeded to insert a large drainage-tube, but found it impossible on account of the close approximation of the ribs. These we tried to separate by various instruments, but in vain. I then examined the wound with the forefinger, and found that as I pressed firmly the ribs began to yield and separate, and then, to my great delight, the finger passed its whole length into the chest cavity, and, on its withdrawal, was followed by a copious discharge of purulent fluid. "Ah!" exclaimed Mr. P., with a gush of relief, "I would have given you five hundred dollars just now to take away your finger, and now, if I had it, I would give you as much for having put it in." Cod-liver oil, 3j, with twenty drops of the muriated tincture of iron, three times daily, was prescribed—a favorite prescription of the writer in such

* Read before the New York State Medical Association, November 19, 1884.

cases. In about two months Mr. P. was entirely restored to health. The chest cavity was twice washed out with warm water slightly carbolized.

CASE II.—Mr. F., twenty-one years of age, commercial traveler, of Jewish race, extremely nervous and timid; previous history good; parents and brothers and sisters healthy. Has been ill for two months. Has slight cough and night-sweats; is greatly emaciated; pulse 120, respiration 32. Has all the physical signs of effusion in right pleuritic cavity. The hypodermic needle withdrew thick, white, inodorless pus. The operative procedure was precisely the same as in Case I, except that the ribs were separated more easily, more quickly, and with less pain, as would be expected from the age of the patient. Rapid and entire recovery ensued. The chest cavity was several times washed out with a weak solution of boracic acid. I was invited to see this patient by Dr. Frank, of Buffalo.

CASE III.—John G., inmate of Buffalo General Hospital, German, forty-five years of age. Habits had been intemperate for many years. Has chronic pleurisy with very large serous effusion. Had been aspirated by Dr. Herman Mynter twice before admission to the hospital. Since admission has been aspirated twelve times in eight weeks. Has been placed upon tonics and diuretics. Chest has been painted often with the tincture of iodine, and the recumbent position has been almost constantly maintained. He has, however, steadily lost ground, and the effusion recurs rapidly after aspiration. Abdominal dropsy and oedema of the lower extremities also become apparent. There is no albuminuria and no cardiac disease. Cirrhosis is suspected. It was decided to introduce a drainage-tube. This was done as in the other two cases, but was not as well borne; for four days he had sinking turns, and for the first two days the discharge was deeply tinged with blood. He began to rally at the expiration of a week, and for three weeks distinctly improved, but again failed, and died five weeks from the date of the operation. The post-mortem examination showed half a pint of bloody serum in the pleural cavity, the costal pleura very red and engorged, the pulmonary pleura covered with thick, false membrane, and the lung pressed upward and backward, and so small and condensed that it was about the size of an adult hand. It did not, however, present any other evidence of disease. The pericardium was pretty fully distended with serous fluid. The left lung and left pleura were healthy. The liver was contracted and cirrhotic. All the other organs healthy.

The writer has had quite an extensive experience in paracentesis thoracis, and has often been annoyed in trying to make a sufficiently large and permanent opening for a drainage-tube of proper caliber. He trusts that he has hit upon a method which will obviate this difficulty for others and himself, and respectfully submits it for consideration and comment to the New York State Medical Association.

MODERN PROGRESS IN MATERIA MEDICA AND THERAPEUTICS.*

By E. R. SQUIBB, M. D.,
BROOKLYN.

[HAVING premised that his twenty-five years' experience in supplying a portion of the medical profession with some of the established articles of the materia medica had enabled him, to a great degree, to ascertain the therapeutical

preferences of a great body of physicians who were quite outside of medical organizations, or were simply enrolled without taking any active part in their proceedings, but that what he had to say on the present occasion was not so much a retrospect founded on this knowledge as a forecast of what progress in the next few years was pointed to by this experience, Dr. Squibb proceeded as follows:]

The public, though much interested in abstruse researches and ingenious speculations and theories of health and disease, is only entertained or amused by them, and the profession not only gets little substantial credit for them, but often has them turned against it in ridicule. All this is becoming better understood and realized, and the physician is looking more and more carefully, not only for knowledge, but for the means of applying it. He makes the accurate investigation of disease, but does not rest there, but tries to control the abnormal conditions found. Much less is heard of expectancy, much less of "Young Physic," than formerly. Active agencies carefully studied and skillfully used are much more common now, and the search after such agencies is even becoming hurtfully keen, so that there is danger of the opposite extreme from the former expectancy.

Instances might easily be given of individuals of no uncommon attainments or opportunities, gifted with neither the polished manners nor liberal morals which so often contribute to one kind of success, but fairly equipped with the known means of controlling disease, who, often in frontier populations, within five or ten years, show to the communities in which they work the utilitarian value of a doctor, and through him of his profession also. Success to his community means success to him and to his profession at large. And the success which begins in the actual results of his skill and labor in his community endures and increases just in proportion to its utilitarian character. Thermometers, urinometers, litmus-paper, test-tubes, and a few reagents, are always found in the orders of such physicians, and plain microscopes, and even sphygmographs, occasionally. Their materia medica proper is commonly simple, the articles not numerous, but effective, and rarely outside of the Pharmacopœia, and their orders for the newest and best advertised remedies are often conditional, always in very small quantities, and, as a general rule, not repeated.

Few will doubt the dependence of the profession for success upon its utility to the public, and very much of this utility must always depend upon therapeutics, and this, in turn, upon the materia medica. Hence, if there be a progress in materia medica and therapeutics, it is an improvement of the very foundation upon which the medical profession rests, and its importance in the future can hardly be overestimated.

Another important reformation that appears to have been slowly and steadily going on in the near past is in the value of the word cure. The old idea of specific or particular diseases and specific cures seems to have undergone considerable modification for the better, not only in the intelligent portion of the people, but also in the medical profession. That diseases are all so many definite entities, for each of which there is a special cure or antidote, if it

* An abstract of a paper read before the New York State Medical Association, November 18, 1884.

could only be discovered, and that incurable diseases are only those for which cures have not yet been discovered, but for which they may be discovered at any time, is a doctrine which common education in the sciences is steadily bringing into a newer and truer light. Many physicians successfully treat disease, if not diseases, but very few undertake cures. Neither do intelligent persons call physicians with the unmodified idea of being cured. But they rather seek for skilled advice, and submit themselves with more or less confidence to be so controlled that they may have the best chances of speedy recovery. And, when well, they are not so often, in their own language—and still more rarely in that of the physician—cured, but have simply recovered. Modern progress seems to indicate that the farther both the public and the profession get away from the old meaning of this word cure, the better, for, when it is properly understood in the modern light of cause and effect, much complex, indiscriminate drugging will be saved, and the dealers in cures—from corn cures to cancer cures—will have their mercantile enterprises better understood. If modern therapeutics is coming to have less and less to do with cures, in the old acceptance of the word, then *materia medica* is surely equally progressive, for there are probably hardly any now who believe in the possibility that any drug should cure any disease, and therefore it is doubtful now whether there be much chance left, in the profession of medicine, at least, for repetitions of the episodes of cundurango, Missisquoi water and mud, and Chian turpentine. But, as the doctrine of cures disappears, the utility and certainty of remedial agents become better established, so that the modern progress is attained in both directions.

Another element in the progress of the near past is a gradual and steady emancipation from the trammels of arbitrary doses of medicines. Physicians are no longer satisfied now with the doses given in the books. With increasing knowledge and broader views they now look for effects, and the time is, perhaps, not far off when the only use of stated doses of medicines will be to know what quantity to begin with. It has come to be very commonly recognized that different persons, and even different conditions of the same person, are very differently susceptible to the action of medicines, and that, within certain limits, quantities must be adjusted almost to each individual case. In three successive cases of confirmed epilepsy in adults, the number of seizures were not sensibly reduced short of 100 grains of bromide of potassium a day in one case, 160 grains in a second case, and 240 grains in the third case, and these quantities produced only moderate bromism. Had the doses of the standard books been adhered to, two out of the three cases would have been unimproved by the medicine.

There are cases wherein the ringing in the ears will be caused by two grains of sulphate of quinine, and there are others which require sixty grains to give this sign of saturation, and there are persons in whom different quantities are required at different times. To treat a recurring malarial fever without recognizing these facts is to fail of success, and discredit both the physician and the medicine, in a considerable number of the most difficult cases, where most credit is to be gained. Dr. W. H. Van Buren,

more than twenty-five years ago, emphasized this liability to be trammelled by arbitrary doses. In the treatment of consecutive syphilis he found a number of patients recovered under the use of 40 grains of iodide of potassium a day. But others were not impressed by less than 100 grains a day, while a few required 480 grains a day to give similar results. His teaching, and that of others who followed him, applying the same principle to other agents, have done much for the modern progress in this important matter of doses, for it is generally realized now among the best therapeutists that no remedy can be properly considered as having failed until it has been pushed to a physiological or a pathological effect.

[Reference was then made to the greater scrutiny now applied by the profession to the purity of the medicinal preparations employed by them, to the growing tendency of physicians to confine themselves within the scope of the *Pharmacopœia*, to the abandonment of complex prescriptions, to the precision with which doses were measured, and to certain limitations of the availability of the alkaloids and the glucosides; and the paper concluded as follows:]

Finally, perhaps the greatest progress of all has been in the power and definiteness of the agents used, and in judging of the manner and effect of using them. Many years ago, when, among the first of these very definite and powerful agents, the American hellebore came into use for controlling the action of the heart, it was objected that its use was merely controlling a symptom of disease without going to the root of the matter at all. The pneumonia went on all the same, and perhaps the depressing action of the drug was simply added to the depressing action of the inflammation, and harm rather than good might rationally result. It took some time to show by actual experience that the drug could be given in controlling quantities without more depression than was needed in a sthenic disease, and that the lowering of the pulse-rate by fifteen to twenty per cent. meant the sending of fifteen to twenty per cent. less of inflammatory blood through an inflamed, congested, and oppressed organ, whose obstructed functions were threatening life, and therefore that treating this pulse symptom was really treating the whole of the disease by controlling its prominent element. It was thus clearly recognizable that, by subtracting one prominent element or symptom from the group which constitute a disease, the bond is broken, and it then tends to disintegration, just as, when an atom or a group of atoms is subtracted from a molecule, it splits up and loses its identity and its reactions.

Then, when bromide of potassium was successful in controlling the seizures of epilepsy, it was objected that it merely controlled the expression of the diseased condition without affecting that condition, since when the medicine was omitted, or was used in too small quantity, the seizures would recur. But in the progress made in the near past it has been abundantly shown that when the bromide is skillfully managed and continued through a long time, with great perseverance and care, for a sufficient length of time after the attacks have ceased, many patients are no longer in the condition which caused the attacks, and that thus, in treat-

ing the principal symptom, the condition causing it has also been treated successfully.

Again, in those agents which simply reduce temperature—take, for example, the use of salicylates in acute rheumatism—the effect is to control one symptom primarily; but it happens that, through the close relationship of symptoms, two others of equal importance are also controlled—namely, the pain and swelling. It is maintained that the disease goes on, and commonly runs its course; but it is admitted that it is occasionally cut short, and that it is almost always rendered comparatively free from high fever, pain, and swelling; that heart damage is less frequent and less serious, and that relapses occur less frequently.

It is needless to multiply examples to show that great progress has been made in the acquisition of definite agents and in the knowledge of how to use them, and should the next ten or twenty years prove as fertile in the resources of the medical art as is indicated by the progress of the past, the profession will occupy a much higher position in the estimation of the public than it now does.

It should not be inferred from the foregoing that all the prominent changes in relation to the materia medica within the past few years have been improvements, or for the good of either the profession or the public, for much doubtful medication has grown into common use among large numbers of physicians who do not seem to stop to think where the mercantile enterprise of the manufacturer is carrying them.

Clinical Reports.

CASES SELECTED FROM THE ORTHOPÆDIC CLASS AT THE NEW YORK POLYCLINIC.

By V. P. GIBNEY, M. D.

Acute Bursitis of the Left Knee of Four Days' Standing; prompt Recovery.—Multiple Syphilitic Dactylitis, with Gummatus Infiltration about Knee and Ankle.—Chronic Diaphysio-epiphysitis at the Proximal End of the Right Tibia, with Chronic Ostitis of the Ninth and Tenth Dorsal Vertebra, in a Child inheriting Syphilis; Recovery of Tibial Disease, with Joint-functions preserved.—Osteous Ostitis (Tuberculous?) at the Proximal End of the Tibia; Burrowing Abscess extending to Joint; subsequently a Typical Case of Chronic Articular Ostitis (White-Swelling).

CASE I.—A boy, seven years of age, apparently in great pain and quite unable to walk, presents this morning a marked fullness over the internal condyle of the left femur, and the circumference is an inch and a half greater here than over the corresponding portion of the right side. There is increased heat, as shown by palpation, and the rectal temperature is $101^{\circ}5'$. There is no fluctuation, but the parts are quite tense, the tenderness is great, and it is easily seen that the synovial cavity is free from distention. This is well shown by comparative inspection, and by a knowledge of the extent of the synovial membrane. It is true that he holds the knee in sharp flexion, and resists attempts at passive extension, although, with a little coaxing, the leg is extended, and when this is done the fullness is not manifest on either side of the tendon of the quadriceps, as you would find in case the effusion were confined to the syno-

vial cavity. Direct concussion also elicits no joint tenderness. Movement, however, in any direction does cause pain. The fullness, you will observe, is circumscribed to a locality above and around the condyle. There is no atrophy of the calf or of the thigh. It will be observed that the boy is sick, is suffering considerably, has a temperature of $101^{\circ}5'$, and that certain soft parts about the knee present signs of an acute lesion. So much, then, for the symptoms and signs now present.

What history have we?

The family is above the average for this class; not that, if a diligent inquiry were instituted, a tuberculous or a specific taint could not be discovered in some remote member of one or the other families, but for all practical purposes these are absent, and the family physician who sends me the case tells me that he knows that the family history is good.

The boy himself has always been regarded as healthy and active on limb. Ten days ago he was absolutely free from limp or halt, and began to complain that evening, after an unusually active day, of a little pain in the neighborhood of the knee; but this disappeared on the following morning, and nothing more was felt in the way of pain or stiffness until four days ago—i. e., he was well until then. The slight pain he felt six days before seemed to return, and he was enabled, by its increased severity, to locate it in and about the inner condyle of the left femur. It grew rapidly more acute, and next day (three days ago) he was confined to his bed, or rather he refused to walk, and the doctor, seeing him, ordered that he keep his bed. It was supposed that he was developing a case of acute articular rheumatism, and on this hypothesis the salicylates were administered unsparingly. Drugs have given no relief, and the impression is that he is growing worse. Hence his appearance at the clinic.

In arriving at a diagnosis, we can first exclude an acute synovitis by the absence of signs already familiar to you; we can exclude a chronic articular ostitis, because the acuteness of the invasion does not belong to a chronic ostitis; we can exclude an acute ostitis, because of the early appearance of tension and fullness in the soft parts; we can exclude a peri-arthritis (cellulitis), because of the circumscribed nature of the tumor, and by the temperature (not high enough); we can exclude, for similar reasons, an acute monoarticular rheumatism. Any one familiar with an acute periarticular rheumatism knows well enough that the lesion does not limit itself to one side of a joint.

By reference to Morris on the joints, you will find figured a bursa on the inner side of the knee, between the internal condyle and the inner head of the gastrocnemius and the semi-membranosus. This bursa sends a process between these two muscles, and is the largest of the popliteal bursae. The description is on page 370 of Morris's work, and just in this connection let me urge a study of this most excellent treatise.

This case I shall refer to the family physician, to whose kindness we are indebted for our study to-day, and our advice will be: rest in bed, rest to the parts by means of a posterior splint—the simpler the better.

The prognosis is favorable, not only for a perfect limb, but for a speedy recovery.*

CASE II.—This female child is fifteen months of age; the father is a seafaring man, and but little is known of his personal history. The mother has been married two years and ten months, has had no miscarriages, has had no primary lesion so far as can be ascertained, but was a great sufferer from headache during pregnancy, and as she was nearing term her hair fell, so

* The patient was reported to me by the doctor in attendance, a few months later, as having recovered very promptly within a month. There was a slight relapse, but this did not interfere with a perfect result.

that she was nearly bald. She did not complain of sore throat, and does not know of any eruption.

The child was a full-term child, but when three weeks of age began to have "snuffles," which, however, lasted only about three weeks. About this time it had an eruption, which was called rubecula, lasting about a week, and disappeared gradually without treatment, and not to reappear.

When seven months of age the great toe of the right foot began to enlarge and to present an inflamed appearance. Soon the index-finger of the left hand; a little later there appeared an infiltration about the left knee. Two months ago the left ankle began to show a similar condition. Two or three weeks ago the ring-finger of the left hand, and within a few days the great toe of the left foot, became involved.

So that we now have for study: 1. The first phalanx of the forefinger, left hand, presenting a marked degree of infiltration with a small cicatrix of an abscess (?). 2. The first phalanx of the ring-finger presents a moderate amount of infiltration, with a little redness of the skin. 3. Over the head of tibia, left side, on the outer aspect, is a somewhat circumscribed infiltration about the size of a half hen's egg, without any redness of the skin and without any fluctuation. 4. Over and around the external malleolus is a marked degree of infiltration without redness of skin. 5. The soft parts about the left ankle are similarly involved, but to a much less extent. 6. The first phalanx of each of the great toes is involved in the same way as the finger, and there are two small cicatrices of recently closed sinuses (?) on the great toe of the left foot, while that of the right foot is free from any such marks. There is no redness of skin on either foot.

The child does not appear to suffer much from pain, and, apart from these deformities, would not cause the mother to seek medical advice. With such a history and with such signs I think the presumption should be that the case is syphilitic, and the treatment should be directed on this supposition.

Accordingly, we prescribe the following mixture, a drachm of which is to be administered three times a day: R Potass. iodidi, 3 ss.; hydrarg. bichloridi, gr. ss.; syr. simplicis, aquæ fontanæ, aa ʒij. M. The ankle and knee joints, of course, do not require any local treatment, and we shall simply keep these joints, so to speak, under observation, expecting a subsidence of the gummata in due time.*
